The ability to convert low energy quanta into a quantum of higher energy is of great interest for a variety of applications such as bioimaging^{1,2}, drug delivery³ and photovoltaics⁴. Although high nonlinear conversion efficiency can be achieved using macroscopic nonlinear crystals, upconverting light at the nanometer scale remains challenging because the subwavelength scale of materials prevents exploiting phase matching processes⁵. Light-plasmon interactions occurring in noble metal nanostructures have offered alternative opportunities for nonlinear upconversion of infrared light, but the conversion efficiency rates remain extremely low due the weak penetration of the exciting fields into the metal⁶. Here we show that the third harmonic generation (THG) from an individual semiconductor indium tin oxide (ITO) nanoparticle is significantly enhanced when coupled within a plasmonic gold dimer. The plasmonic dimer acts as a receiving optical antenna⁷, confining the incident far field radiation into a near field localized at its gap. Meanwhile, the ITO nanoparticle located at the plasmonic dimer gap acts as a localized nonlinear transmitter upconverting three incident photons at frequency ω into a photon at frequency 3ω . This hybrid nanodevice provides third harmonic generation enhancements of up to 10^6 folds compared to an isolated ITO nanoparticle, with an effective third order susceptibility up to $3.5 \times 10^3 \text{ nm}^2/\text{V}^2$ and conversion efficiency of 0.0007%. We also show that the upconverted third

harmonic emission can be exploited to probe the near-field intensity at the plasmonic dimer gap.

Efficiently converting multiple low energy photons into a photon of higher energy is of great interest in many areas of science and technology. At macroscopic scales, coherent conversion processes are intensively exploited for upconverting tunable laser light⁸ and for fast label-free imaging of biological samples⁹. At nanoscopic scales, luminescence upconversion subwavelength crystals can play the role of carriers for intracellular drug delivery¹⁰ and are considered as promising candidates to overcome the Shockley-Queisser efficiency limit of single-junction solar cells^{4,11}. Technological advances realized in nanoengineering of noble metals have offered new opportunities for nonlinearly upconverting infrared pulsed light within nanometric volumes *via* the exploitation of coherent harmonic generation processes from plasmonic structures excited at resonance⁶. While most of seminal works have focused on the nonlinear intrinsic responses from plasmonic structures¹²⁻¹⁴, only few recent studies have investigated so far the enhanced nonlinear extrinsic responses provided by plasmonic couplings⁵. Such configurations are particularly suitable for electrical¹⁵ and optical¹⁶ control of nonlinear properties from bulk materials adjacent to plasmonic structures, or for plasmon-enhanced generation of coherent extreme-ultraviolet light from gas jets¹⁷. Despite significant advances, achieving high harmonic conversion efficiencies of light from nonlinear nanostructured materials remains a challenge to address.

In this letter, we introduce and experimentally demonstrate the viability of a novel subwavelength harmonic conversion system made of a single indium tin oxide nanoparticle decorated with a plasmonic dimer (Fig. 1a). Although the THG from an isolated ITO nanoparticle is relatively weak, localized plasmonic coupling dramatically enhances by several orders of magnitude its three-photon upconversion, which enables to unambiguously discriminate the third harmonic signal from the ITO nanoparticle from the strong intrinsic nonlinear metallic background¹⁸⁻²⁰. Due to the non-absorbing nature of the nonlinear generation processes, the third harmonic scattering from the ITO nanoparticle is mainly sensitive to the local intensity excitation in the plasmonic gap region, thus enabling an

accurate probing of near-field intensities with a far-field method.

The nonlinear upconversion nanosystems were realized *via* two-steps electron-beam lithography and a combination of etch-down and lift-off methods, with a well-controlled spatial alignment. Single 25 nm diameter ITO nanoparticles were generated by ion beam etching followed by a lift-off procedure for creating well aligned gold dimer decorations (Fig. 1b). This led to the completion of the nonlinear upconversion system made of an ITO nanoparticle at the gap of a plasmonic dimer presented in Fig. 1b,c. Due to the non-directional deposition nature of the ITO sputtering process, the combination of etch-down and lift-off methods is essential to realize the hybrid nanostructures presented in this work, hence the differences in the fabrication approach compared to those recently used for subwavelength plasmonic mapping^{21,22} and probing²³ investigations, or for controlling the optical responses of plasmonic antennas by nanomaterial loading²⁴.

Finite-difference time-domain (FDTD) simulations exploiting the total-field scattered-field formulation were performed to provide the spatial distribution of the intensity enhancement and extinction spectrum of the fabricated dimers (Fig. 1d,e). The dimer models are generated from the SEM pictures such as the one presented in Fig. 1c, whereas the ITO nanoparticles are considered ideal 25 nm diameter cylinders localized at the position determined from the SEM pictures. The optical dielectric functions of Au, Cr (adhesion layer), SiO₂ (substrate) and ITO are fitted to experimental data^{25,26}. As highlighted in previous works²⁷, the introduction of a dielectric nanoparticle at the gap of a metallic optical antenna dimer leads to a spectral red-shift of its plasmonic resonance (Fig. 1e).

The linear experimental characterization of the fabricated structures in array configuration (112 nanostructures per array, pitch of 2 μ m) was performed using a commercial Fourier transform infrared spectroscopy (FTIR) apparatus, (see Supplementary Section S2 for more information). The corresponding extinction spectra (defined as 1-transmission) for the 35 nm nanorod dimer with and without an ITO nanoparticle at its gap is presented in Fig. 1f. A slight red-shift of the resonance peak position is observed for both configurations compared to the numerical predictions of Fig. 1e, which can be attributed to minor defects related to the

fabrication process (thickness of the gold layer, roughness...), but the shapes of the measured extinction cross sections agree well with the simulated spectra. From Fig. 1f, one can also observe that the fundamental excitation wavelength set for the nonlinear investigations matches with the plasmonic resonance of the nanorod dimer not coupled to an ITO nanoparticle.

We started our nonlinear experimental investigations by measuring the THG from an isolated ITO nanoparticle (see Supplementary Section S3 for more information). Under excitation at frequency ω , the third order ITO susceptibility²⁶ $\chi^{3\omega} = 3.36 \text{ nm}^2/\text{V}^2$ induces a nonlinear polarization $\mathbf{P}^{3\omega} = \epsilon_0 \chi^{3\omega} \mathbf{E}^\omega \mathbf{E}^\omega \mathbf{E}^\omega$, which in turns generates a radiation of intensity $I^{3\omega} \propto |\mathbf{P}^{3\omega}|^2$. As expected, a fundamental femtosecond excitation at $\lambda = 1500 \text{ nm}$ gives rise to the instantaneous third harmonic ITO response centred at $\lambda = 500 \text{ nm}$ presented in Fig. 2a. From this spectrum, the THG radiated power is estimated to be $1.94 \times 10^{-20} \text{ W}$, corresponding to an upconversion efficiency of $5.8 \times 10^{-10} \%$. This weak efficiency is dramatically enhanced when the single ITO nanoparticle is decorated with a 35 nm gap nanorod plasmonic dimer (Fig. 2b) under parallel polarized excitation. The third harmonic peak intensity generated by the hybrid upconversion system is increased by 6 orders of magnitude compared to an isolated ITO nanoparticle, leading to a third harmonic power of $2.17 \times 10^{-14} \text{ W}$ and an upconversion efficiency of $7 \times 10^{-4} \%$. Notice that unlike the linear characterization performed by FTIR spectroscopy, all nonlinear measurements with hybrid nanostructures have been conducted on single entities. Such huge increase of the nonlinear signal essentially results from the high excitation intensity enhancement created by plasmonic coupling²⁸, but can also be viewed as an improvement of the third order ITO susceptibility $\chi^{3\omega}$ (see Supplementary Section S6 for more discussions). Exploiting the experimental data, we compute a third order effective susceptibility of $3543 \text{ nm}^2/\text{V}^2$ for the 25 nm ITO nanoparticle decorated with the plasmonic dimer, which is a susceptibility 7 order of magnitude higher than those reported with nonlinear macroscopic crystals²⁹.

As non-negligible intrinsic third harmonic responses from plasmonic antennas were recently reported¹⁸⁻²⁰, careful attention has been devoted to quantify the intrinsic third harmonic background from the plasmonic dimers by conducting extensive sets of multi-wavelength measurements (data available in Supplementary Section S4) and nonlinear FDTD simulations for the limiting cases with either $\chi_{\text{Au}}^{(3)}$ or $\chi_{\text{ITO}}^{(3)}$ set to zero (data available in Supplementary Section S8). These results combined with a gap size dependence analysis and an extensive set of multi-wavelength measurements indicate that THG from the ITO nanoparticle coupled to the plasmonic dimer is 16 times higher (THG upconversion efficiency 3 orders of magnitude higher, data provided in Supplementary Section S4) than the THG background from the metallic dimer itself, thus confirming that the nonlinear signal mainly originates from ITO³⁰. The nonlinear phenomenon responsible for the upconversion process requires the instantaneous capture of three infrared photons to generate a green photon, hence a cubic dependence of the radiated third harmonic with excitation intensity is expected. This trend is corroborated by the experimental measurements presented in Fig. 2c, which show that the THG intensity from the upconversion hybrid system is sensitive to the third power of the fundamental incident light. Unlike luminescent nanocrystals⁴, the upconverted light from the hybrid nanosystem does not exhibit any saturation limitation, and, on the contrary, increasing the fundamental incident power leads to improving the conversion efficiency. This observation is a direct consequence of the scattering nature of harmonic generation mechanisms as opposed to the absorption nature of luminescence processes. Nevertheless the nonlinear upconversion efficiency is currently limited by the laser damage threshold of the hybrid nanosystems, which prevents achieving third harmonic conversion efficiency greater than $7 \times 10^{-4} \%$ (more discussion available in Supplementary Section S7).

As an immediate application of high relevance for nanophotonics, we accurately quantify the excitation intensity enhancement η for various nanodimers (Fig. 3a), when their gaps are coupled to single emitters, by using an ITO nanoparticle as a probe of the near-field plasmonic intensity. From the numerical simulations shown in Fig. 3b, one can observe that any increase of the dimers' gaps leads to a reduction of plasmonic intensity enhancements,

and therefore to weaker third harmonic responses from the ITO nanoparticle. Such expectations are corroborated by the third harmonic spectral measurements displayed in Fig. 3c,e, where the THG intensity drastically decreases with increasing gap dimensions. Exploiting these data, the intensity enhancement factor η can be computed as the cube root of the ratio between the third harmonic power from the ITO nanoparticle with and without the plasmonic antenna investigated. This is further discussed in the Supplementary Section S5. The experimental values determined for η are presented in Fig. 3d,f together with numerical predictions. Excellent agreement was found between the experimental observations and the simulated data for all the probed designs. As expected from the third harmonic spectra of Fig. 2b and Fig. 3c,e, the highest intensity enhancements are provided by the 35 nm gap nanorod and 30 nm gap nanocylinder dimers, with experimental values for η of 103.6 and 49.4 respectively, and numerical predictions of 119.5 and 55.1, respectively. Lower enhancement factors were measured for the 55 nm gap nanorod and 40 nm gap nanocylinder dimers due to weaker electromagnetic couplings for increasing gaps. These excellent agreements between experimental and numerical intensity enhancements demonstrate that single nonlinear nanoparticles can play the role of subwavelength near-field probes.

In summary, we have introduced and experimentally highlighted the viability of a novel nanoscale upconversion system based on a single nonlinear nanometric particle decorated with a plasmonic motif. This nanosystem provides nonlinear upconversion enhancements up to 10^6 fold compared to an isolated ITO nanoparticle, and enable to unambiguously discriminate the nonlinear signal emitted by the ITO nanoparticle from the intrinsic nonlinear metallic background. While the plasmonic antennas presented here exhibit narrow-band resonances, tunable third harmonic upconversion nanosystems could be realized by implementing a nonlinear nanomaterial at the gap of broadband plasmonic antenna designs³¹. Finally, we demonstrated that a nonlinear nanoparticle can be used as a near-field nanoprobe to quantify the hot spot intensities in plasmonic dimers when single emitters are placed at their gaps, thus introducing a new form of nonlinear enhanced light-matter interactions at the

nanoscale and bridging the gap between the theoretical predictions of field enhancement and experimental electromagnetic nanometrology.

Methods

Sample fabrication. The third harmonic upconversion nanosystems composed of an ITO nanoparticle decorated with a plasmonic dimer were realized via combination of electron-beam lithography with etch-down and lift-off approaches, accompanied by precise alignments. Indeed, a pure lift-off approach prevents achieving nanometric size particles with dimensions smaller than 30 nm diameter via sputtering because of its non-directional deposition nature. Therefore, a quartz substrate was first covered with a 40 nm ITO film by sputtering. Hereafter, high resolution circular nanodots and alignment markers were defined in hydrogen silsesquioxane resist on the substrate by electron-beam lithography. Ion beam etching (argon ions) of the ITO layer was then performed to generate single 25 nm diameter nanoparticles, as presented in Fig 1b. Then, the sample was coated with polymethylmethacrylate and rod/ cylinder nanodimer shapes centred on a single ITO nanoparticle were defined in the resist, followed by a thermal evaporation of 2 nm chromium adhesion layer and 40 nm gold. A final lift-off step led to the completion of the upconversion system made of an ITO nanoparticle trapped in the gap of a plasmonic dimer, as presented in Fig. 1b,c. More details about nanofabrication are available in Supplementary Section S1.

Numerical simulations. We performed 3D FDTD simulations using the commercial software FDTD solution v8.6 (Lumerical Inc. Vancouver, Canada). The SEM pictures of the dimers were imported into the software to generate the dimer model according to the fabricated dimensions. The ITO nanoparticles, meanwhile, were considered as ideal Ø25nm cylinders placed at the position according to the SEM pictures. The optical dielectric functions of the different materials are taken from tabulated data: Au, Cr, SiO₂ and ITO^{25,26}. The dielectric dispersion of the materials was fitted in the spectral range from 1000 nm to 2000 nm by a 6-coefficient model, allowing a tolerance of 0.1 and enforcing passivity.

All simulation boundaries were set as perfect matched layers (PML) to replicate a single dimer over a semi-infinite substrate scenario. The solver-defined total-field scattered-field (TFSF) source was used to reduce computation effort since it allows defining the plane-wave excitation within the volume

enclosing only the dimer. For the linear simulations shown, the TFSF box had a size $800 \text{ nm} \times 500 \text{ nm} \times 80 \text{ nm}$. The x -polarized plane-wave excitation was incident normal to the dimer from the semi-infinite free-space, i.e., propagating along $-z$. The incident temporal pulse had spectral components ranging from 1000 nm to 2000 nm (i.e. central wavelength 1500 nm, and bandwidth of 1000 nm), and thus, its pulse length is $\sim 6.64 \text{ fs}$. A conformal non-uniform mesh was used to map accurately the details of the model. The TFSF volume default grid was $7 \text{ nm} \times 7 \text{ nm} \times 2 \text{ nm}$. For the dimer region, the volume with dimensions $650 \text{ nm} \times 340 \text{ nm} \times 50 \text{ nm}$ was discretized with a cubic grid of $4 \text{ nm} \times 4 \text{ nm} \times 2 \text{ nm}$. An even smaller cubic grid of $0.5 \text{ nm} \times 0.5 \text{ nm} \times 2 \text{ nm}$ was overridden in the region enclosing the ITO nanoparticle and the gaps between the ITO particle and each arm of the dimer. A finer mesh size along z of 0.5 nm was applied for the Cr layer. The maximum simulation time was set to 300 fs. The time stepping stability factor was set to 0.99, which corresponded to a time step of $\delta t = 0.00095 \text{ fs}$. The residual energy in the simulation box volume was at least 50 dB lower than its peak value to ensure that the continuous wave information obtained by discrete Fourier transformations was valid. A standard convergence test was done to ensure negligible numerical errors originated from the PML distance, the non-uniform meshing, or the monitor sampling.

The extinction cross section was calculated by the sum of the power flowing outward through a volume enclosing the TFSF source (scattering cross section) and the net power flowing inward through a rectangular cuboid inside the TFSF volume enclosing the dimer (absorption cross section). The average intensity within the ITO nanoparticle was obtained from a 3D field monitor. To generate the intensity enhancement color maps, a 2D field profile monitor recorded the field on the xy middle cross section plane. More linear and nonlinear simulations are presented in Supplementary Section S8.

Experimental setup. The inverted microscope developed for this work uses a Yb:KGW femtosecond PHAROS laser system as a pump of a collinear optical parametric amplifier ORPHEUS with a LYRA wavelength extension option (Light Conversion Ltd, Lithuania, pulse duration 140 fs, repetition rate 100 kHz). For nonlinear experiments, the fundamental incident wavelength is focused on the sample plane by a 0.6 NA microscope objective, and the backward-emitted third harmonic generation at 500 nm is collected via the same objective. More information about the experimental setup is available in Supplementary Section S3.
