Abstract

The wide use of titanium dioxide nanoparticles (TiO$_2$ NPs) in industrial applications requires the investigation of their effects on human health. In this context, we investigated the effects of nanosized and bulk titania in two different crystalline forms (anatase and rutile) \textit{in vitro}. By colony forming efficiency assay, a dose-dependent reduction of the clonogenic activity of Balb/3T3 mouse fibroblasts was detected in the presence of rutile, but not in the case of anatase NPs. Similarly, the cell transformation assay and the micronucleus test showed that rutile TiO$_2$ NPs were able to induce type-III foci formation in Balb/3T3 cells and appeared to be slightly genotoxic, whereas anatase TiO$_2$ NPs did not induce any significant neoplastic or genotoxic effect. Additionally, we investigated the interaction of TiO$_2$ NPs with Balb/3T3 cells and quantified the \textit{in vitro} uptake of titania using mass spectrometry. Results showed that the internalization was independent of the crystalline form of TiO$_2$ NPs but size-dependent, as nano-titania were taken up more than their respective bulk materials.

In conclusion, we demonstrated that the cytotoxic, neoplastic and genotoxic effects triggered in Balb/3T3 cells by TiO$_2$ NPs depend on the crystalline form of the nanomaterial, whereas the internalization is regulated by the particles size.

Keywords: titanium dioxide nanoparticles; cytotoxicity; morphological neoplastic transformation; genotoxicity; micronucleus; uptake
**Introduction**

Titanium dioxide nanoparticles (TiO$_2$ NPs, titania) are currently used in a variety of applications ranging from the paper industry, where they confer whiteness and opacity in cellulose papers (Huang *et al*., 2011), to the production of antifogging and self-cleaning glasses and plastics (Howarter and Youngblood, 2008). TiO$_2$ NPs are also used as food color additives and flavor enhancers (Weir *et al*., 2012) and in various cosmetics owing to their ability to absorb and scatter UV light (Wolf *et al*. 2003; Shi *et al*. 2013). Due to their photocatalytical properties titania can additionally be employed in the degradation of pollutants in water treatment implants (Chong *et al*. 2010).

Nevertheless, the wide use of TiO$_2$ NPs, which naturally can occur in three different crystalline forms namely anatase, rutile and brookite, raised concern in the last years. Based on the evidence that titania can induce lung cancer in rats, the International Agency for Research on Cancer (2010) classified TiO$_2$ NPs as possibly carcinogenic to humans (group 2B). In fact, lung tumors (Xu *et al*., 2010), broncho-alveolar adenomas and cystic keratinizing squamous cell carcinomas (Mohr *et al*. 2006) developed following inhalation and instillation of, respectively, rutile and anatase TiO$_2$ NPs.

In addition, nowadays several studies report that titania might be harmful to human health. Rutile titania impaired the viability of human amnion cells (Saquib *et al*., 2012), skin fibroblasts and human epidermoid carcinoma cells (Uchino *et al*., 2011), but cytotoxicity was observed also in Chinese hamster fibroblasts (Hamzeh and Sunahara, 2013). Similarly, anatase TiO$_2$ NPs induced oxidative stress, apoptosis and impairment of the mitochondrial activity in *in vitro* human-derived glial and lung cells (Aueviriyavit *et al*., 2012; Huerta-Garcia *et al*. 2014). Moreover, anatase exerted cytotoxic effects in Chinese hamster fibroblasts (Chen *et al*. 2014) and in murine
osteocells (Bernier et al., 2012; Di Virgilio et al., 2010b). However, anatase was not cytotoxic in human intestinal cells (De Angelis et al., 2013), as well as in nasal mucosa cells (Hackenberg et al., 2010) and in lymphocytes (Hackenberg et al., 2011).

Analogously, no conclusive results on the genotoxic potential exerted in vitro by anatase and rutile NPs have been reported. Increased DNA strand breaks and chromosome aberrations were detected in human intestinal, amniotic and epidermal cells (Saquib et al., 2012; Shukla et al., 2011), and in Chinese hamster ovary and lung fibroblasts exposed to the two types of titania (Di Virgilio et al., 2010; Hamzeh and Sunahara, 2013). Conversely, anatase TiO$_2$ NPs were not able to induce DNA damage in human nasal mucosa (Hackenberg et al., 2010) and peripheral blood lymphocytes (Hackenberg et al., 2011).

Although many studies have been published showing experimental evidences of the toxic potential of TiO$_2$ NPs, the role played by the crystalline form of titania in the toxic mechanisms is still unclear. In this study, we evaluated the effects induced in vitro by TiO$_2$ NPs in Balb/3T3 mouse fibroblasts which after exposure to carcinogens become tumourigenic forming morphologically transformed colonies (foci type III). Their ability to induce cancer in vivo is detectable by injecting the transformed cells in nude mice and observing their growth as sarcomas (Kurzepa et al., 1984; Saffiotti & Ahmed 1995). This cell model was selected among Syrian Hamster Embryo (SHE) cells, C3H10T1/2 and Bhas42 in vitro models (Kerckaert et al., 1996; Isfort & LeBoeuf, 1996; Balls & Clothier, 2010) alternative to the use of animals able to detect morphological neoplastic transformation potential induced by chemicals and nanomaterials (NM).

In particular, we compared the effects exerted by two crystalline forms (anatase and rutile) of nanosized titania with their respective bulk materials, focusing not only on the cytotoxicity and
the morphological transformation induced by TiO₂ NPs, but investigating also the genotoxicity of titania and their internalization in Balb/3T3 cells. The in vitro cytotoxicity was assayed performing the non-colorimetric Colony Forming Efficiency (CFE) test, while Cell Transformation Assay (CTA) evaluated morphological neoplastic transformation induced by anatase and rutile TiO₂ NPs. To investigate if TiO₂ NPs are able to induce chromosomal damage, we performed the cytokinesis-blocked micronucleus (CBMN) assay, and the uptake of titania in Balb/3T3 cells was investigated by Inductively Coupled Plasma-Mass Spectrometry (ICP-MS), which allowed us to perform a correlation between the amount (expressed as mass and number of particles) of TiO₂ NPs internalized and their toxic potential.

Materials and Methods

Synthesis and characterization of TiO₂ NPs

Pure anatase and rutile TiO₂ NPs were obtained by hydrolysis and oxidation of TiCl₃ as previously described (Cassaignon et al., 2007; Valsami-Jones et al., 2008; Sweeney et al. 2014). Stock suspensions of nanosized anatase (An-10), nanosized rutile (Ru-10), bulk anatase (BAN) and bulk rutile (BRU) were characterized in deionized water by Dynamic Light Scattering (DLS) and Transmission Electron Microscopy (TEM). For TEM analysis, each sample was dropped onto ultrathin Formvar-coated 200-mesh copper grids (Ted Pella, Inc.; USA) and left to air dry before image acquisition was performed with a JEOL 2100 electron microscope (JEOL USA, Inc.; USA). Zeta-potential was also recorded for all the samples at pH 7. To further investigate their behavior, TiO₂ NPs were characterized by centrifugal liquid sedimentation (CLS) in deionized water and at increasing time points (0 – 24 – 48 – 72 h) incubation in complete cell culture medium. Before each analysis stock suspensions of TiO₂ NPs were bath-sonicated (10
min) and then aliquots were added to deionized water or to complete cell culture medium to obtain 0.1 mg/ml test suspensions. CLS characterization was performed by using the DC24000UHR centrifugal particle sedimentation (CPS Instruments; The Netherlands) operated at a speed of 30,000 x g in an 8-24 % wt sucrose density gradient.

**Cellular system**

Immortalized Balb/3T3 mouse fibroblasts (clone A31-1-1) purchased from Hatano Research Institute (Japan). Cells were cultivated under normal cell culture conditions (37°C; 5% CO₂; 95% humidity) in complete cell culture medium composed of Modified Essential Medium (MEM) 1X (Invitrogen; Italy), supplemented with 10% (v/v) foetal bovine serum – Australian origin (Invitrogen; Italy) and 1% (v/v) antibiotics (Invitrogen; Italy). Sub-confluent cells (70-80 %) were passaged weekly in tissue culture-treated flasks (BD Falcon; Italy).

**Colony Forming Efficiency (CFE) test**

To investigate the potential in vitro cytotoxicity of TiO₂ NPs in Balb/3T3 mouse fibroblasts, Colony Forming Efficiency (CFE) assay was performed as previously described (Uboldi et al., 2012). Deionized water and sodium chromate (1000 µM) were used as solvent (C solv) and positive (C +) control, respectively. After TiO₂ NPs were bath-sonicated for 10 min, aliquots of the stock suspensions were directly pipetted into the culture dishes to obtain the desired test concentrations (1 – 5 – 10 µg/ml) and cells were exposed to titania for 24 h and 72 h. The number of colonies was scored using the software-operated colony counter GelCount™ (Oxford Optronix Ltd.; UK). Data were normalized to the solvent control and expressed as % CFE [(average of treatment colonies / average of solvent control colonies) × 100]. The standard
error of the mean (SEM) was calculated for 3 independent experiments and 3 replicates for each experimental point (SEM = standard deviation / square root of the number of replicates). Statistical significance was calculated by one-way ANOVA analysis with Bonferroni post hoc test (GraphPad Prism5 statistical software, GraphPad Inc.; USA).

**Cytokinesis-blocked micronucleus (CBMN) test**

To test the genotoxic potential of TiO$_2$ NPs, we performed the CBMN test as already described (Uboldi et al. 2012). Cells were exposed to the fixed concentration of 10 µg/ml for each TiO$_2$ NPs. The data (3 independent experiments and 3 replicates for each experiments performed) were analyzed by manually scoring the presence of micronuclei (MN) in 1000 binucleated (BN) cells. The results are expressed as the number of binucleated micronucleated (BNMN) cells per 1000 binucleated cells (BNMN/1000 BN cells) ± SEM. Statistical analysis was performed by one-way ANOVA with Bonferroni post hoc test (GraphPad Prism5 statistical software, GraphPad Inc.; USA), and differences versus C solv (ultrapure water) were considered statistically significant at $p < 0.05$.

**Cell Transformation Assay (CTA)**

Cell transformation assay (CTA) was performed to test if TiO$_2$ NPs can induce morphological neoplastic transformation in Balb/3T3 fibroblasts since they become tumourigenic forming morphologically transformed colonies (foci type III). CTA is considered a powerful tool to investigate in vitro the morphological neoplastic transformation induced by chemicals and nanomaterials (Vanparys et al., 2010; Ponti et al., 2013). Recently, its development into an OECD test guideline was recommended (EURL ECVAM, 2012).
As previously described (Uboldi et al., 2012; Ponti et al., 2013), Balb/3T3 cells were seeded in 100 mm-Petri dishes (3.34x10^3 cells/ml; 6 ml/dish; 3 independent experiments and 5 replicates per concentration) and exposed for 72 h to TiO_2 NPs (Table 1). Untreated Balb/3T3 cells and cells exposed to 4 µg/ml of 3 - methylcholanthrene (Sigma-Aldrich; Italy) were used as negative and positive controls, respectively. After fixation (4% (v/v) of formaldehyde in PBS) and staining (10% (v/v) Giemsa solution in ultrapure water), the morphologically transformed colonies (type-III foci) were scored as described by the International Agency for Cancer research IARC Working-Group (IARC/NCI/EPA, 1985). Transformation results were expressed as transformation frequency (T_f) using the formula T_f = [A/(B x C x D)], where A = total number of type III foci per treatment; B = CFE(%)/100; C = Plating Efficiency (%)/100; D = number of cell seeded multiplied per the number of plates; Plating Efficiency (%) = [(number of colonies formed in the control x 100) / 200], and 200 is the total number of cells initially seeded in each dish. Statistical analysis was performed applying the F-Fisher exact test and results were considered significant versus solvent control only when p < 0.05.

**Uptake of TiO_2 NPs**

To verify and quantify the uptake of TiO_2 NPs in Balb/3T3 mouse fibroblasts, the Inductively Coupled Plasma-Mass Spectrometry (ICP-MS) technique was performed using a 7700 series ICP-MS (Agilent Technologies Inc.; Italy). 5x10^5 Balb/3T3 cells were seeded in 75 cm^2 tissue culture treated flasks (BD Falcon; Italy) in 10 ml of complete cell culture medium, and treated with a nominal concentration of 0.5 mg/ml TiO_2 NPs.

After 72 h exposure, the medium was collected for each test sample and stored at -20°C. The cells were washed twice with 5 ml PBS, and each wash was collected in a separate tube and
frozen for further analysis. Balb/3T3 cells were trypsinized, suspended with 9 ml of complete culture medium and then counted using a TC10 automated cell counter (Bio-Rad; Italy). After centrifugation, the supernatant was collected into a new tube and the dried pellet stored at -20°C. Before performing ICP-MS analysis, the frozen samples were restored at RT. To quantify the amount of Ti internalized, the cellular pellet was mineralized with Aqua Regia (HNO₃: HCl, 1:3 v/v) and digested in a microwave (Discover SP-D; CEM SRL; Italy). Two independent experiments (3 replicates each experiment) were carried out and results were expressed as picograms (pg) of uptaken Ti /cell using the formula \((A/B) \times C\), where \(A = [\text{Ti}]\), expressed as ppb, at the end of the experiment; \(B = \text{total number of cells at the end of the experiment}\) and \(C = \text{conversion factor ppb to pg}\). We also calculated the number of internalized TiO₂ NPs /cell using the formula \(D/B\), where \(D = \text{number of TiO₂ NPs at the end of the experiment}\). D was calculated transforming the concentration of titania found in the cellular pellet in mass of nanoparticles. This value was transformed into number of nanoparticles knowing that titania are insoluble (De Angelis et al., 2013) and assuming that most of the particles are spherical and well dispersed. Statistical analysis was performed applying t-test and results were considered significant when \(p < 0.05\).

**Results**

**Characterization of TiO₂ NPs: hydrodynamic diameter, PDI and Z-potential**

DLS measurements (Table 1) showed that the mean size diameter of as-synthesized An-10 and Ru-10 was 51.42 ± 0.35 nm and 134.40 ± 1.02 nm respectively while it was 333.80 ± 2.90 nm and 734.20 ± 15.56 nm for BAN and BRU respectively. Polydispersity index (PDI) for these samples were ranging between 0.17 ± 0.01 and 0.24 ± 0.04, indicating that TiO₂ NPs were
relatively well dispersed in suspension. The Z-potential values at pH 7.0 for An-10 (-5.64 ± 0.77 mV), Ru-10 (+0.04 ± 0.13 mV) and BRU (-6.62 ± 3.90 mV) indicated a tendency to agglomerate/aggregate, whereas BAN resulted highly negative (-48.40 ± 1.04 mV) and stable.

TEM characterization (Figure 1) indicated that An-10 is composed by primary particles of ovoid and spherical shape with a mean size diameter ranging from 11 nm to 18 nm, while Ru-10 showed more elongated particles ranging from 10 nm to 35 nm. BAN and BRU were highly aggregated and composed of particles with different geometry, whose size ranged from 60 nm to 400 nm (BAN) and from 250 nm to 600 nm (BRU).

Further physico-chemical characterization of TiO₂ NPs suspensions (100 µg/ml) in deionized water and in cell culture medium supplemented with 10% serum was performed by CLS (Table 2). Freshly prepared An-10 (t = 0 h) resulted in nanoparticles of the same mean size range either in water or in culture medium (49 ± 21 nm and 46 ± 15 nm, respectively), while a slight but not significant increase in its hydrodynamic diameter was observed after 24 – 48 – 72 h incubation. Similarly, Ru-10 showed no significant increase in mean diameter when the value in water was compared to the particles size measured in the presence of serum proteins and at increasing time points. Analogously, bulk particles did not significantly increase their mean size in the presence of serum proteins (BAN = 260 ± 20 nm and BRU = 755 ± 180 nm) compared to deionized water (243 ± 16 nm and 717 ± 55 nm, respectively).

In deionized water, DLS measurements of An-10, RU-10 and BRU are in agreement with CLS data except for the hydrodynamic diameter of BAN. When TiO₂ NPs were diluted in complete culture medium, both Ru-10 and BAN displayed a significantly different hydrodynamic diameter (p < 0.01 and p < 0.001, respectively) in comparison to the native stock suspensions. Moreover,
CLS analysis showed that at increasing time points the presence of serum did not significantly change the mean size diameter of TiO₂ NPs.

**In vitro cytotoxicity of TiO₂ NPs: evaluation of the clonogenic potential**

At 24 h exposure, none of the investigated TiO₂ NPs significantly impaired the formation of Balb/3T3 colonies. Compared to deionized water, which was used as C solv (100% CFE ± 3.02), a slight but not significant CFE reduction (Figure 2) was observed in Balb/3T3 cells exposed to 5 µg/ml Ru-10 (95.96% CFE ± 5.99) and to 5 µg/ml and 10 µg/ml BRU (97.17% CFE ± 5.21 and 96.97% CFE ± 2.6, respectively).

In contrast, 72 h exposure of Balb/3T3 cells to Ru-10 and BRU at 5 µg/ml and 10 µg/ml doses significantly reduced the CFE: 5 µg/ml Ru-10 impaired the CFE to 73.7% CFE ± 3.62 and 10 µg/ml Ru-10 to 80.22% CFE ± 4.81. Similarly, 5 µg/ml and 10 µg/ml BRU affected the formation of Balb/3T3 colonies to 78.24% CFE ± 2.78 and to 79.38% CFE ± 3.97, respectively. A non-significant impairment of CFE was observed following 72 h exposure to An-10. In fact, compared to the C solv (100% CFE ± 5.84), 5 µg/ml and 10 µg/ml reduced the scored Balb/3T3 colonies to 92.85% CFE ± 3.38 and to 89.64% CFE ± 7.0, respectively. In addition, a statistically non-significant cytotoxic effect was also observed in the presence of 1 µg/ml Ru-10 (82.21% CFE ± 8.54) and 1 µg/ml BRU (92.0% CFE ± 7.53). Taken together, our results indicated that the crystalline form (rutile) might be responsible for TiO₂ NPs cytotoxicity in Balb/3T3 mouse fibroblasts.

**Genotoxicity and morphological neoplastic transformation induced by TiO₂ NPs**
Since the concentration of 10 µg/ml resulted sub-toxic or non-toxic for all the tested titania, it was selected as the most suitable concentration for genotoxicity and morphological neoplastic transformation tests. Using CBMN test, we observed that in the presence of TiO$_2$ NPs, the nuclear division index (NDI; Figure 3A) did not significantly change as compared to C solv (NDI = 2.02) and confirmed that, for each experimental condition, Balb/3T3 cells replicated at least one time during the exposure period, as recommended by the Test Guideline 487 (OECD, 2010). The analysis of micronuclei (MN) induction, as indicator of chromosomal damage, showed that a statistical significant ($p < 0.001$) result in comparison with C solv was observed only after exposure to 10 µg/ml Ru-10 and to the positive control 0.15 µg/ml MMC (Figure 3B). We further investigated the morphological neoplastic transformation potential of TiO$_2$ NPs by performing the in vitro cell transformation assay (Figure 4). Compared to C solv (Tf = 1.4 x10$^{-4}$ ± 0.1) Ru-10 induced statistically significant dose-dependent increasing transformation frequency. Similarly, BRU resulted transforming Balb/3T3 cells, and the highest Tf was scored at the highest tested dose (3.8 x10$^{-4}$ ± 0.2 at 10 µg/ml). Although An-10 and BAN slightly enhanced type-III foci formation, their effect was not statistically significant.

**TiO$_2$ NPs – Balb/3T3 interaction: uptake quantification**

Balb/3T3 were exposed to treatment suspensions at the theoretical concentration of 0.5 mg/ml for 72 h and in order to quantify the real titanium concentration, the treatment suspensions were analysed by ICP-MS. As shown in Figure 5A, Ru-10 (real concentration 0.51 ± 0.01 mg/ml) seems to be the most consistent with the expected theoretical concentration; the measured An-10 and BAN (0.55 ± 0.01 mg/ml and 0.44 ± 0.01 mg/ml, respectively) were slightly different from the theoretical concentration, but the difference was not statistically significant. BRU, in contrast,
appeared as the treatment suspension that more significantly \((p < 0.001)\) differed from the theoretical concentration \((0.71 \pm 0.02 \text{ mg/ml versus } 0.5 \text{ mg/ml expected})\). This behaviour was probably due to the higher size distribution and higher tendency to aggregate as compared to the other titania tested (Table 1, 2).

Interestingly, when the number of TiO\(_2\) NPs uptaken per cell was calculated (Figure 5B), nanosized anatase and rutile titania were internalized more significantly \((p < 0.001)\) compared to their bulk counterparts: An-10 resulted being the most uptaken nanoparticles \((1.07 \times 10^8 \pm 2.56 \times 10^6 \text{ NPs})\), followed by Ru-10 \((1.93 \times 10^7 \pm 1.44 \times 10^6 \text{ NPs})\), BAN \((3.26 \times 10^5 \pm 6.6 \times 10^3 \text{ NPs})\) and BRU \((7.14 \times 10^4 \pm 5.3 \times 10^3 \text{ NPs})\). Additionally, the number of anatase TiO\(_2\) NPs, either in the nanorange or in the bulk form, was statistically significant \((p < 0.001)\) compared to rutile.

Coherently, the quantification of the amount of Ti, expressed as pg/ml, still present in the collected supernatant at the end of the exposure period (Figure 5C) showed that BAN and BRU contained more Ti \((5246.17 \pm 114.03 \text{ pg/ml and } 5895.15 \pm 110 \text{ pg/ml, respectively})\) as compared to An-10 \((299.68 \pm 27 \text{ pg/ml})\) and Ru-10 \((1291.48 \pm 63 \text{ pg/ml})\). Consistently, the amount of Ti (pg/cell) internalized by Balb/3T3 mouse fibroblasts (Figure 5D) was higher in Ru-10 and An-10 \((5.06 \pm 0.1 \text{ pg/cell and } 4.15 \pm 0.1 \text{ pg/cell, respectively})\) than in BAN \((0.69 \pm 0.1 \text{ pg/cell})\) and BRU \((0.52 \pm 0.06 \text{ pg/cell})\).

Taken together, the uptake quantification data showed a correlation with the hydrodynamic diameter of the particles with a size-dependent pattern. The nanosized titania, which displayed the lower hydrodynamic diameter as shown in Table 2, were more easily internalized by Balb/3T3 than their respective bulks, indicating that size plays a role in the process.

Interestingly, although An-10 was uptaken by Balb/3T3 mouse fibroblasts as efficiently as Ru-10, the internalization of the particles did not correlate with the toxicity data, which showed
indeed a slightly more significant effect in the presence of nano-rutile titania, thus suggesting that the toxicity is triggered by the crystalline form of TiO$_2$ NPs.

**Discussion**

Although TiO$_2$ NPs are currently used in numerous industrial applications, a careful evaluation of their toxic potential is still needed. In this context, we studied the potential cytogenotoxicity, morphological neoplastic transformation and internalization of TiO$_2$ NPs, and we showed that their crystalline form is a key parameter in their toxicity effect in Balb/3T3 fibroblasts. By colony forming efficiency assay, under our experimental conditions, cytotoxicity was not observed at 24 h exposure in the presence of titania, whereas at 72 h incubation 5 and 10 µg/ml nanosized and bulk rutile titania significantly affected the formation of Balb/3T3 colonies. Similar effects are already reported in the literature (Table 3). Sweeney and co-authors (2014) reported that the membrane integrity of TT1 human alveolar type-I-like epithelial cells was not affected by nanosized anatase and rutile titania, the same that was used in the present study. In contrast, Ru-10 seemed to have a greater pro-inflammatory activity because it stimulated a higher IL-6 and MCP-1 secretion compared to An-10 (Sweeney *et al*. 2014). At 1 – 5 – 10 µg/ml by MTT assay, Saquib and co-authors (2012) demonstrated that rutile TiO$_2$ NPs impaired the viability of WISH human amnion cells, and the toxicity at 24 h was comparable to our CFE results at 72 h. These different results can be explained taking into consideration the size of the particles: while Saquib *et al*. (2012) studied TiO$_2$ NPs with hydrodynamic diameter of 30 nm, our rutile titania ranged from 60 - 80 nm (Ru-10) to 730 - 750 nm (BRU) and that could have deferred the cytotoxic effect.
Our results show that the cytotoxicity of TiO$_2$ NPs might not be simply triggered by the size of the particles, but that the crystalline form plays a role as well. In fact, while we measured a significantly higher internalization of anatase TiO$_2$ NPs, it was the rutile crystalline form that induced cytotoxicity, genotoxicity and morphological transformation in Balb/3T3 fibroblasts. This effect was already reported in V79 cells, where within 24 h rutile TiO$_2$ nanorods (420 nm) reduced the cell survival more severely than 365 - 460 nm anatase ones (Hamzeh and Sunahara, 2013). Nevertheless, size-related cytotoxic effects exerted by rutile TiO$_2$ NPs in normal human skin fibroblasts, in Chinese hamster ovary and in rat basophilic leukemia cells were also reported. As shown by Uchino *et al.* (2011), 20 nm rutile titania resulted more cytotoxic than 250 nm ones, and the effect positively correlated with the amount of particles internalized. Similarly, by ICP-MS we also detected a more significant internalization of nano-rutile TiO$_2$ NPs compared to its bulk, which could explain the higher toxicity induced by Ru-10 compared to BRU. Under our experimental conditions, we showed that Balb/3T3 colony formation is not affected upon exposure to low concentrations (1 - 5 - 10 µg/ml) of bulk and nano-anatase titania. Similarly, Kim *et al.* (2010) reported that, up to 500 µg/ml, anatase TiO$_2$ NPs were not able to inhibit A549 and L-132 colony formation. Moreover, 15 nm TiO$_2$ NPs (10 - 100 µg/ml) increased the survival of NIH-3T3 cells as shown by CFE assay (Huang *et al.*, 2009). Taken together these results confirm that the crystalline structure has a key role in the cytotoxicity of TiO$_2$ NPs.

In contrast, previous studies reported that also anatase titania exert cytotoxic effects (Table 3). Cytotoxicity was detected in A549 cells exposed to anatase TiO$_2$ NPs; analogously, anatase titania affected the mitochondrial integrity of human-derived glial cells (Huerta-Garcia *et al.* 2014) and V79 hamster lung fibroblasts (Chen *et al.* 2014).
In addition to their cytotoxic potential, TiO$_2$ NPs were already reported to induce genotoxic effects (Table 3). Anatase TiO$_2$ NPs of 20 nm slightly enhanced MN formation in binucleated CHO-K1 cells after 24 h treatment (Di Virgilio et al., 2010), and in HaCaT cells 10 μg/ml of 200 nm TiO$_2$ NPs significantly increased the MN rate (Jaeger et al., 2012). Additionally, Shukla et al. reported that the dose-dependent increase in MN frequency and the induction of oxidative DNA lesions observed in A431 human epidermal cells were correlated to an enhanced lipid peroxidation following exposure to 170 nm anatase TiO$_2$ NPs (Shukla et al., 2011). Moreover, Falck and co-authors (2009) showed that anatase TiO$_2$ NPs (hydrodynamic diameter below 20 nm) enhanced the MN frequency in human derived bronchial cells BEAS-2B.

Our results partially confirmed these data, as we observed MN induction in Balb/3T3 at longer exposure periods (48 h), and only the chromosome aberrations induced by Ru-10 were statistically significant. In contrast, nano-rutile TiO$_2$ NPs filaments, with primary size 10 x 40 nm, were reported to not increase MN frequency in BEAS-2B cells (Falck et al. 2009).

Additionally, we showed that the morphological neoplastic transformation is more related to the crystalline form than to the size of the particles: rutile TiO$_2$ NPs were able to significantly induce type-III foci formation in Balb/3T3 cells, whereas anatase TiO$_2$ NPs did not. To our knowledge this is the first in vitro study directly highlighting the neoplastic transformation potential of TiO$_2$ NPs, as previous investigations reported the same effect but via DNA damage analysis and, therefore, via a secondary genotoxic mechanism.

Additionally, we demonstrated that rutile and anatase TiO$_2$ NPs are internalized by Balb/3T3 cells, showing thus that the reduced colony forming efficiency and the formation of MN and type-III foci were due to a direct interaction between titania and cells. However, while we observed that the cytotoxic and genotoxic potential of TiO$_2$ NPs can be associated with their
crystalline form, the uptake of TiO$_2$ NPs seemed to depend on their size. The nanosized An-10 and Ru-10, which by DLS were shown to have a smaller hydrodynamic diameter compared to their bulk counterparts, were significantly more uptaken compared to BAN and BRU. Even if further studies on NPs dosimetry are necessary to better understand kinetics of nanomaterials and to measure the real administrated, delivered and internalized concentrations (Cohen et al., 2013; DeLoid et al., 2014), our ICP-MS data are in good agreement with previous published results. Aggregates/agglomerates of rutile TiO$_2$ NPs were observed by TEM in cytoplasmic vesicles in A549 (Auevuriyavit et al., 2012) and WISH cells (Saquib et al., 2012). Shukla et al. (2011) and Hackenberg et al. (2010) detected TiO$_2$ NPs in the nucleus of, respectively, human epidermal cells and human nasal mucosa cells, while in BEAS-2B cells the massive presence of particles in the perinuclear region was associated to an altered gene transcription induced by titania that, consequently, blocked the nuclear pores (Park et al., 2008).

Taken together, our results showed that the crystalline form has a role in toxicity in Balb/3T3 mouse fibroblasts. Rutile titania was slightly more toxic than anatase TiO$_2$ NPs. These results might be explained taking into account the different reactivity of the two crystalline forms we have investigated. In fact, rutile TiO$_2$ NPs are more photocatalytic than anatase and consequently, are able to generate higher amounts of oxygenated free radicals on their own surface (Fenoglio et al., 2009; Lipovsky et al., 2012). Moreover, since the ability of several types of nanoparticles to trigger genotoxic effects has been demonstrated to be linked to their ROS induction (Magdolenova et al., 2014), this can explain the results we have obtained by exposing BALB/3T3 mouse fibroblasts to TiO$_2$ NPs. Nevertheless, other physicochemical properties (such as size, mono/polydispersity or surface charge) might play a synergistic role in the differences existing between the mechanism of toxicity of rutile and anatase.
Results available in the literature are difficult to compare mainly due to different factors that can alter the properties of nanomaterials such as their source, the synthesis protocol used, size, coating of NPs and their behavior in culture media. Therefore, further investigation on cyto-genotoxicity of titania using a methodological approach linked to a systematic physico-chemical characterization is still required.

**Funding**

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 214478 (NanoReTox).

**Acknowledgements**

The authors would like to acknowledge Dr. Deborah Berhanu for TiO₂ NPs synthesis and Dr. Fabio Franchini for performing ICP-MS analysis.

Figure legend

**Figure 1. TiO$_2$ NPs stock suspensions shape and size determination.** TEM micrographs of the as-synthesized TiO$_2$ NPs indicated that An-10 (A) is composed by egg-shaped particles of 11 - 18 nm, while Ru-10 (B) is more elongated and the particles have a mean size diameter of 10 - 35 nm. BAN (C) and BRU (D) were highly aggregated and composed of particles with different geometry.

**Figure 2. Cytotoxicity induced by TiO$_2$ NPs in Balb/3T3 mouse fibroblasts.** Colony Forming Efficiency (CFE) was performed on Balb/3T3 cells exposed for 24 h and 72 h to increasing concentrations (1 – 5 – 10 µg/ml) of TiO$_2$ NPs. Cytotoxicity was not observed after 24 h exposure, while at 72 h 5 µg/ml and 10 µg/ml Ru-10 and BRU significantly impaired the formation of Balb/3T3 colonies. An-10 and BAN did not exert any cytotoxic effect even after 72 h incubation. The positive control sodium chromate (1000 µM) induced complete cell death (0% CFE). Mean of 3 independent experiments including 3 replicates each ± SEM. Data were compared to C solv (deionized water, 100% CFE) and evaluated by one-way ANOVA with Bonferroni post hoc analysis. ** $p < 0.01$.

**Figure 3. Genotoxic potential of TiO$_2$ NPs by CBMN assay.** The Nuclear Division Index (A) demonstrated that cells have divided at least one time during exposure to TiO$_2$ NPs (24 h exposure with 10 µg/ml titania). The number of binucleated micronucleated cells (BNMN) scored in 1000 binucleated cells containing one of more micronuclei (B) indicated that An-10, Ru-10 and BRU induced MN formation, but only Ru-10 was statistically significant. The
statistical significance was evaluated by one-way ANOVA with Bonferroni post hoc analysis in respect to C solv. Mean of 3 independent experiments and 3 replicates each ± SEM. Mitomycin C (0.1 µg/ml) was used as positive control (C+). *** $p < 0.001$.

Figure 4. Morphological neoplastic transformation induced by TiO$_2$ NPs in Balb/3T3 mouse fibroblasts. All the investigated TiO$_2$ NPs induced type-III foci formation and the data are expressed as transformation frequency (Tf). Tf was slightly more severe and statistically significant in the presence of Ru-10 and BRU compared to their anatase counterparts. The statistical significance was evaluated by F-Fisher exact test and compared to C solv. Mean of 3 independent experiments including 5 replicates each ± SEM. 3-Methylcholanthrene (4 µg/ml) was used as positive control (C+). * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

Figure 5. TiO$_2$ NPs – cell interaction: quantification by ICP-MS. Compared to the theoretical (0.5 mg/ml), the measured concentration of TiO$_2$ NPs in the treatment suspensions (A) was significantly different only in BRU (*** $p < 0.001$). Based on the real concentrations measured, the number of TiO$_2$ NPs uptaken in each cell was calculated (B) and showed that An-10 and Ru-10 were internalized more efficiently (*** $p < 0.001$) than BAN and BRU; moreover, the number of An-10 TiO$_2$ NPs uptake per Balb/3T3 cell was significantly higher than Ru 10 (### $p < 0.001$) and BAN particles were taken up more (§§§ $p < 0.001$) than BRU. Accordingly, the ICP-MS quantification of the amount of Ti, expressed as pg/ml, in the collected supernatant (C) revealed that bulk materials and the rutiles were the less internalized titania (*** $p < 0.001$). The quantification of the amount of Ti (pg/cell) uptaken by the total amount of Balb/3T3 mouse fibroblasts (D) after 72 h exposure showed that nanosized TiO$_2$ NPs were internalized more (***
$p < 0.001$) than bulk, but interestingly showed that Ti from Ru-10 was significantly higher ($^\# p < 0.05$) than An-10. Mean of 2 independent experiments ± SEM.
