(Received 8 August 2000; accepted 8 December 2000)

Using tunable vacuum–ultraviolet radiation from a synchrotron, the decay pathways of the valence electronic states of CF$_2$X$_2^+$ (X=Cl, H, Br) in the range 10–25 eV have been determined by threshold photoelectron–photoion coincidence spectroscopy. The ions are separated by a linear time-of-flight mass spectrometer. Coincidence spectra are recorded continuously as a function of energy, allowing threshold photoelectron spectra and yields of the fragment ions to be obtained. At fixed photon energies, spectra are recorded with improved time resolution, allowing the mean total translational kinetic energy, $\langle KE\rangle$, into some dissociation channels to be determined. By comparing the $\langle KE\rangle$ values for single-bond fragmentations with those predicted for the limiting extremes of a statistical and an impulsive dissociation, information on the nature of the photodissociation dynamics can be inferred. The excited states of all three parent cations show some evidence for isolated-state behavior. With CF$_2$Cl$_2^+$ and CF$_2$H$_2^+$, this is apparent from the form of the ion yields in the range 11–15 eV, whereas interpretation of the yields for CF$_2$Br$_2^+$ is hampered by an absence of thermochemical data. New upper limits at 298 K for the enthalpies of formation of CF$_2$H$^+$ (593±3 kJ mol$^{-1}$) and CF$_2$Br$^+$ (570±9 kJ mol$^{-1}$) are obtained. At higher photon energies, smaller fragment ions are formed following cleavage of more than one bond. With CF$_2$Cl$_2$ and CF$_2$Br$_2$, the appearance energies of the fragment ions are close to the thermochemical energy for production of that ion with neutral atoms, suggesting that these ions form by bond-fission processes only. With CF$_2$H$_2$, the one ion unambiguously assigned, CFH$^+$, can only form at certain energies with molecular neutral fragments (i.e., CFH$^+$ + HF), involving simultaneous bond-breaking and bond-making processes. The $\langle KE\rangle$ values for cleavage of a single C–F or C–X bond suggest a relationship between the part of the molecule where ionization occurs and the bond that breaks; impulsive values of $\langle KE\rangle$ are more likely to be obtained when the breaking bond lies close to the part of the molecule from which ionization occurs, statistical values when ionization occurs further away from the breaking bond. Furthermore, for all CF$_2$X$_2^+$ cations there is a trend from impulsive to statistical behavior as the photon energy is increased. © 2001 American Institute of Physics.

I. INTRODUCTION

In a recent publication,$^1$ a comprehensive study of the fragmentation of the outervalue states of CCl$_3$F$^+$, CCl$_3$H$^+$, and CCl$_3$Br$^+$ using coincidence techniques was presented. In this paper, coverage of the halo-substituted methanes is extended to the CF$_2$X$_2^+$ (X=Cl, H, Br) series where interest, like the previous study, derives from the fact that such molecules lie between the “small” and “large” molecule limits. A vacuum–ultraviolet (VUV) fluorescence study of these molecules found no evidence for parent ion emission,$^2$ indicating that the excited valence states of the parent ion primarily exhibit nonradiative decay processes such as dissociation into fragment ions. The fragmentation of VUV-excited CF$_2$Cl$_2^+$ and CF$_2$H$_2^+$ has been extensively studied both by electron-impact mass spectrometry (EIMS) and photoionization mass spectrometry (PIMS),$^3$-$^6$ but studies have not been performed on CF$_2$Br$_2^+$. The He I, and in some cases He II, photoelectron spectra of all three molecules have been measured by several groups,$^{11}$-$^{20}$ but no threshold photoelectron spectra (TPES) have been reported. TPES can be used to probe the effects of autoionization to near-threshold electrons in the titled molecules. In this paper, the TPES and the first threshold photoelectron–photoion coincidences (TPEPICO) study of the three molecules is presented, extending both the non-state-selective mass spectrometry studies$^7$-$^{10}$ and the work of Kischlat and Morgner who performed a few PEPICO experiments on CF$_2$Cl$_2^+$ using He I radiation as a photoexcitation source.$^{21}$ The development of tunable VUV radiation from synchrotron sources has enabled the use of TPEPICO spectroscopy to provide state selectivity in the parent cation. Performed at sufficient
mass resolution, the TPEPICO technique can also yield the total mean translational kinetic-energy release, \(<KE>_t\), into ionic dissociation channels. Thus, insight into the partitioning of energy into dissociation products may be gained. The aim of this work is to determine the identity of dominant fragmentation channels and the mechanism of dissociation of individual excited valence states of CF₂X₂⁺.

II. EXPERIMENT

Radiation in the range 10–30 eV from the 2 GeV synchrotron storage ring at the U.K. Daresbury Laboratory provides the tunable source of VUV radiation. The coincidence apparatus, comprising a threshold-energy electron analyzer and a linear time-of-flight (TOF) mass spectrometer, has been described in detail in previous publications. The two analyzers for electrons and ions are mounted collinearly within an evacuated stainless-steel chamber (base pressure \(5 \times 10^{-8}\) Torr) attached to the storage ring of the synchrotron via a 1 m Seya–Namioka monochromator (best achievable resolution = 0.05 nm). One of two 1200 lines mm⁻¹ gratings, mounted back to back inside the vacuum, can be used. The high-energy grating is used for most experiments where \(\lambda < 100\) nm (\(E > 12.4\) eV), the medium-energy grating for \(80 < \lambda < 120\) nm (10.3–15.5 eV). Sample gas is admitted into the vacuum chamber using a precision needle valve, operating pressures ranging from 1 to \(5 \times 10^{-5}\) Torr. Extraction of the electrons and ions from the interaction region through identical 20-mm-diam apertures is achieved by a 20 V cm⁻¹ electrostatic field. The ions pass through a two-stage accelerating region configured to satisfy the first-order spatial focusing condition, and a 182-mm-long field-free region. The threshold electrons are focused by a striaidancy analyzer onto the entrance slit of a 127° cylindrical postanalyzer, which serves primarily to remove on-axis energetic electrons. The mass-selected ions are detected by a pair of microchannel plates (Hamamatsu F4296-10), the threshold electrons by a channeltron (Phillips X818 BL). The amplified signals from both detectors can either be measured independently [for total ion yield or threshold photoelectron (TPE) spectroscopy] or in delayed coincidence (for TPEPICO spectroscopy). The two modes of operation occur simultaneously, using a dedicated personal computer (PC) equipped with a counter card and a purpose-built time-to-digital converter (TDC) card (Alan Burleigh of Pulsitron Ltd.). The best time resolution of the TDC card in its current configuration is 8 ns. CF₂H₂ and CF₂Cl₂, manufactured by Aldrich and Fluorochem, respectively, were supplied in lecture bottles and used without further purification. CF₂Br₂, from Aldrich, is a liquid at room temperature and pressure, and several freeze–pump–thaw cycles were applied to it before use.

Measurements can be made either at fixed or varying photon energies. In the scanning-energy mode, flux-normalized TPEPICO, TPE, and total ion yield spectra are obtained in the range 10–25 eV. The VUV photon flux is monitored by measuring the fluorescence from a sodium salicylate window mounted behind the interaction region, using an EMI 9718 B photomultiplier tube in the dc mode. The scanning-energy TPEPICO spectrum accumulate as a three-dimensional histogram, where the coincidence count (color)

III. ENERGETICS OF THE KEY DISSOCIATION CHANNELS

The energetics of the key dissociation channels (\(\Delta H^0\)) for CF₂X₂ → A⁺ + n₁B + n₂C + e⁻, with X=Cl, H, Br, and \(n_1=0,1,2,3\) and energies of the outervalence electronic states of the parent ions of CF₂X₂ are given in Table I. The thermochemical threshold, \(\Delta H^0\), was determined by calculating the difference in the heats of formation (\(\Delta H^0\)) of products and reagents. The effects of internal energies are avoided if values for \(\Delta H^0\) at 0 K are used. In cases where this was possible, values were taken from the JANAF tables. For CF₂Br₂ and all of its ions except Br⁺, values of \(\Delta H^0\) at 0 K were not available, hence, values at 298 K, taken from Lias et al., were used instead. We should note that the values for CClF⁺ (703 kJ mol⁻¹), CFCl⁺ (1017 kJ mol⁻¹), CCI⁺ (1243 kJ mol⁻¹), CF₂H⁺ (611 kJ mol⁻¹), and CFH⁺ (1121 kJ mol⁻¹) were obtained only by indirect methods. No thermodynamic data are available for CF₂Br⁺, CF₂Br⁺, CFBr⁺, CF₂Br⁺, and CFB⁺, so the thermochemistry of dissociation channels involving these fragments is unknown. Unless stated otherwise, the energies of the valence states of CF₂Cl⁺, CF₂H⁺, and CF₂Br⁺ were taken from Cvitas, Gusten, and Klasinc, Potts et al., and Cvitas et al., respectively.

The internal energies (\(E_{\text{internal}}\)) of CF₂Cl₂ and CF₂H₂ were calculated using the equation

\[ E_{\text{internal}} = 1.5k_BT + \sum \frac{E_i}{\exp(E_i/k_BT)} - 1, \]

where \(1.5k_BT\) is the contribution from the rotational degrees of freedom at temperature \(T\), \(k_B\) is Boltzmann’s constant, and \(E_i\) is the energy of the \(i\)th vibrational mode. The required vibrational frequencies were taken from the JANAF tables. At 298 K, the internal energies for CF₂Cl₂ and CF₂H₂ were

A. **CF$_2$Cl$_2$**

**TPES**

As described in the preceding paper, the electronic configuration of CF$_2$Cl$_2$ is $(3a_1)^2(3a_2)^2(3b_1)^2(3b_2)^2(4a_1)^2$ $(4a_2)^2(4b_1)^2(4b_2)^2$, where the numbering scheme does not include core orbitals. A TPES of CF$_2$Cl$_2$ was recorded from 11.8 to 24.5 eV on the high-energy grating [Fig. 1(a)]

calculated to be 0.09 and 0.05 eV, respectively. An equivalent calculation was not required for CF$_2$Br$_2$ (see Sec. IV C 3).

### IV. RESULTS

**A. CF$_2$Cl$_2$**

**1. TPES**

As described in the preceding paper, the electronic configuration of CF$_2$Cl$_2$ is $(3a_1)^2(3a_2)^2(3b_1)^2(3b_2)^2(4a_1)^2$ $(4a_2)^2(4b_1)^2(4b_2)^2$, where the numbering scheme does not include core orbitals. A TPES of CF$_2$Cl$_2$ was recorded from 11.8 to 24.5 eV on the high-energy grating [Fig. 1(a)]
tion, electrons arising indirectly from autoionization processes will be detected provided their energy is close to 0 eV, i.e., \( A + h\nu \rightarrow A^+ + e^- \) (0 eV). Below 15 eV, the TPE and He I spectra of CF\(_2\)Cl\(_2\) are quite similar, indicating that autoionization is not an important process; this assumes that the ionization cross sections are unchanged between threshold and 21.22 eV. In the TPES, the \( \tilde{A} \) state at 12.55 eV has a slightly low intensity while the \( \tilde{C} \) state at 13.45 eV has a slightly high intensity. These observations indicate that the effect of autoionization producing threshold-energy electrons among the lower valence states varies as \( \tilde{X} \rightarrow \tilde{C} \rightarrow \tilde{B} \rightarrow \tilde{D} \rightarrow \tilde{A} \). Above 15 eV, the peaks in the threshold spectrum have a significantly higher relative intensity than those in the He I spectrum, indicating that autoionization is more important at these higher energies.

2. Scanning-energy TPEPICO experiments

The scanning-energy TPEPICO spectrum was also recorded from 11.8 to 24.5 eV at a photon resolution of 0.3 nm and an ion TOF resolution of 64 ns. While the fragment ions CF\(_2\)Cl\(^+\), CFCl\(_2\)\(^+\), CF\(_2\)\(^+\), CFCI\(^+\), and CF\(^+\) are detected, neither the parent ion nor the fragments CCl\(^+\) and CCI\(_2\)\(^+\) are observed at any photon energy. Ion yields [Figs. 1(b) and 1(c)] and breakdown diagrams (Fig. 2) were constructed by the method previously outlined. The \( \tilde{X} \) to \( \tilde{C} \) states fragment exclusively to CF\(_2\)Cl\(^+\), the \( \tilde{D} \) and \( \tilde{E}/\tilde{F}/\tilde{G} \) states to CF\(_2\)Cl\(^+\) and CFCI\(^+\), the \( \tilde{H}/\tilde{I} \) states to CF\(_2\)\(^+\), and the \( \tilde{J} \) state to CFCI\(^+\).

Appearance energies determined from the ion yields are given in Table II along with values obtained by EIMS or PIMS studies. The AE measured for CF\(_2\)Cl\(^+\), a sharp onset at 11.95±0.05 eV, is in excellent agreement with previous PIMS measurements of Ajello, Huntress, and Rayerman,\(^4\) Jochims, Lohr, and Baumgärtel,\(^5\) and Schenk, Oertel, and Baumgärtel\(^6\) (11.99, 12.10, and 11.96±0.03 eV, respectively). It should be noted, however, that the value quoted by Schenk, Oertel, and Baumgärtel\(^6\) is the higher of the two they quote. Their lower value, 11.81 eV, is assigned to the threshold energy for the process CF\(_2\)Cl\(_2\)→CF\(_2\)Cl\(^+\)+F\(^-\) and cannot, therefore, be compared with our study since ions without associated electrons cannot be detected in the TPEPICO experiment. Using electron-impact ionization, Baker and Tate\(^3\) determined an AE of 12.8±0.2 eV, ~0.9 eV greater than the values obtained using photons. The discrepancy is probably due to the effect of the near-threshold Wannier law.\(^31\) We comment that it is now well established that due to secondary effects such as electron–ion recombination resulting in the variation of ionization cross section with energy close to threshold,\(^31\) energy thresholds are more accurately measured using photon sources. The thermochemical dissociation energy (\( \Delta_H^0 \)) is 11.76 eV (Table I). A comparison of this value with the AE is not meaningful since the oscillator strength associated with production of the parent ion is small below ~11.9 eV, the adiabatic ionization energy of CF\(_2\)Cl\(_2\) being 11.73 eV.\(^14\) Since the lowest dissociation threshold (CF\(_2\)Cl\(_2\)→CF\(_2\)Cl\(^+\)+Cl+e\(^-\)) lies at 11.76
eV, the majority of the Franck–Condon region of the \( \text{CF}_2\text{Cl}_2^+ \) \( X^2B_2 \) ground state is dissociative and, as a consequence, the parent ion is not detected.

The AE measured for \( \text{CFCl}_3^+ \), a shallow onset at 14.2 ± 0.3 eV, is in good agreement with the values of Ajello, Huntress, and Rayerman\(^5\) and Jochims, Lohr, and Baumgartel\(^6\) 13.81 and 14.15 eV, respectively. However, it is 1.2 eV lower than that of Baker and Tate\(^3\), and significantly higher than the accurate measurement of Schenk, Oertel, and Baumgartel\(^6\) report two experimental values, 13 and 14 eV, whose highest of three values, 13.30 ± 0.05 eV.\(^6\) The value of Baker and Tate\(^3\) is probably high because electrons are used as the excitation source. The discrepancy with Schenk’s measurement\(^6\) may be due to the possibility that \( \text{CFCl}_3^+ \) can also be produced by ion-pair formation \( (\text{CF}_2\text{Cl}_2^+ + \text{Cl}^-) \), although this process was not discussed. The thermochemical dissociation energy for \( \text{CFCl}_3^+ \) to \( \text{CFCl}_2^+ + \text{Cl}^- \) is 13.15 ± 0.4 eV, which is lower than our value for the appearance energy. Under this circumstance it is pertinent to compare the two values since the oscillator strength associated with production of the parent ion is relatively high at 13.13 ± 0.3 eV. Any barrier in an exit channel of a potential-energy surface involving a single-bond cleavage is likely to be much lower than 1 eV. Hence, it is thought that the 1 eV difference between the appearance energy and the thermochemical threshold arises from rapid nonstatistical fragmentation, between 113 and 14 eV, of \( \text{CF}_2\text{Cl}_2^+ \) to \( \text{CFCl}_2^+ \), following the removal of a Cl lone-pair electron. The same phenomenon was observed in the fragmentation of the lower valence states of \( \text{CFCl}_3^+ \), resulting in an appearance energy for \( \text{CCl}_3^+ \) significantly higher than the value of \( \Delta H^0 \) associated with \( \text{CCl}_3 \) to \( \text{CCl}_4^+ + \text{F}^- \).\(^1\)

The AE measured for \( \text{CF}_2^+ \), a shallow onset at 17.5 ± 0.4 eV, agrees acceptably with previous measurements. There are two possible channels for the formation of \( \text{CF}_2^+ \): \( \text{CF}_2\text{Cl}_2 \rightarrow \text{CF}_2^+ + \text{Cl}^- + e^- \), \( \Delta H^0 = 14.34 \) eV, and \( \text{CF}_2\text{Cl}_2 \rightarrow \text{CF}_2^+ + 2\text{Cl}^- + e^- \), \( \Delta H^0 = 16.82 \) eV. Comparison with the AE indicates that \( \text{CF}_2^+ \) is probably formed by the higher-energy process. It should be noted, however, that Schenk, Oertel, and Baumgartel\(^6\) report two experimental values, 14.9 ± 0.3 and 16.65 ± 0.1 eV, the lower of which is attributed to \( \text{CF}_2\text{Cl}_2 \rightarrow \text{CF}_2^+ + \text{Cl}^- + e^- \). Since the process is not detected by the TPEPICO experiment, the lower AE probably arises from ion-pair formation, \( \text{CF}_2\text{Cl}_2 \rightarrow \text{CF}_2^+ + \text{Cl}^- + e^- \), \( \Delta H^0 = 13.23 \) eV. The AE measured by us for \( \text{CFCl}_3^+ \) production, 18.7 ± 0.3 eV, is significantly higher than any of the previous measurements, apart from Schenk, Oertel, and Baumgartel\(^6\) whose highest of three values is 18.60 ± 0.05 eV. It is likely that below ∼18.6 eV, the PIMS experiments of Schenk, Oertel, and Baumgartel\(^6\) were detecting \( \text{CFCl}_3^+ \) produced by ion-pair dissociation processes. Indeed, they attribute their lower two AEs, at 15.2 ± 0.3 and 17.50 ± 0.05 eV, to \( \text{CF}_2\text{Cl}_2 \rightarrow \text{CFCl}_3^+ + \text{Cl}^- + e^- \) and \( \text{CF}_2\text{Cl}_2 \rightarrow \text{CFCl}_3^+ + \text{Cl}^- + e^- \), respectively. The AE measured by us for the TPEPICO experiment, 18.7 ± 0.3 eV, is significantly higher than the thermochemical dissociation energies associated with the two possible dissociation channels, \( \text{CFCl}_3^+ + \text{Cl}^- + e^- \) at 17.63 eV and \( \text{CFCl}_3^+ + \text{F}^- + e^- \) at 15.07 eV. Hence, the likely dominant reaction cannot be determined.

The ion yield for \( \text{CF}^+ \) has poor statistics. The AE of 20.3 ± 0.4 eV is in reasonable agreement with that given by Baker and Tate\(^3\), 19.5 ± 0.5 eV, and higher values obtained

by Jochims, Lohr, and Baumgärtel, and Schenk, Oertel, and Baumgärtel, and Schenk, Oertel, and Baumgärtel report are due to ion-pair processes. Although the ClCâ¦ â¦ Cl ions have been observed in both EIMS and PIMS experiments, the TPEPICO data presented here have failed to detect it. This is due either to a relative lack of sensitivity associated with the TPEPICO experiment, or that the ClCâ¦ â¦ Cl ions detected in the EIMS experiments are only formed by ion-pair processes.

### 3. Fixed-energy TPEPICO experiments

TPEPICO-TOF spectra were measured for CF2Cl2â CF2Cl+ + Cl at energies of 12.28, 12.56, 13.19, 13.48, 14.42, and 16.25 eV, corresponding to initial formation of the X, Λ, Σ, B, C, D, and E/F/G states of the parent ion. In addition, a TPEPICO-TOF spectrum was recorded for CF2Cl+ â CFCl2+ + F at 16.25 eV. Experimental values for ⟨KE⟩ and ⟨f⟩, determined as the fraction of the available energy released into translational energy of the products, and values of ⟨f⟩, determined for the statistical, pure-impulsive, and modified-impulsive cases, are given in Table III. Allowance has been made in the fitting procedure for the fact that each Cl atom exists as two isotopomers ([35]Cl 75%, [37]Cl 25%). The statistical frequencies were calculated using known vibrational frequencies for ν1 (1507 and 1352 cm−1 for CF2Cl+ and CFCl3+, respectively) and ν5 (1406 and 1142 cm−1, respectively) modes. The vibrational frequencies of the other four modes are unknown, so values for the isoelectronic BF2Cl and BFCl2 molecules were used. The maximum values of ⟨f⟩, determined for the modified-impulsive model were calculated assuming that the polyatomic fragment (CF2Cl+ or CFCl3+) initially has a regular tetrahedral structure with bond angles of 109.5°. The minimum values were obtained assuming planar geometry with bond angles of 120°. In calculating ⟨f⟩, for both the pure- and modified-impulsive cases, isotopically averaged masses were used.

The values of ⟨KE⟩ and ⟨f⟩, determined for CF2Cl+ fit well to a pure-impulsive model below 13.5 eV, although the slightly high values of ⟨f⟩, calculated at photon energies of 12.28 and 12.56 eV may be indicative of a small contribution of modified-impulsive behavior. The ⟨KE⟩, determined for dissociation of CF2Cl+ XΣ+ → XΣ+ B2 at 14.42 eV fits to a statistical/impulsive hybrid mechanism, while dissociation of CF2Cl+ EΣ+ → EΣ+ B2 at 16.25 eV appears to be purely statistical. Overall, there is a transition from impulsive to statistical behavior as the photon energy increases. The ⟨KE⟩, determined for CFCl3+ fits more closely to a pure-impulsive than to a statistical model.

### B. CF2H2

#### 1. TPES

As described previously, the electronic configuration of CF2H2 in C2v symmetry is (2a1)2(1b2)2(3a2)2(2b1)2(1a2)2(4a1)2(3b2)2(2b2)2, where the numbering scheme does not include core orbitals. A TPES of CF2H2 was measured from 12.4 to 27.5 eV on the high-energy grating at a resolution of 0.3 nm [Figs. 3 and 4(a)]. Peaks were observed at 13.3, 15.5, 19.1, and 24.0 eV corresponding to the formation of the XΣ2+, ΛΣ1/2, Σ1/2, and G1/2 states of the parent ion. The resolution in our experiment was not sufficient to resolve some of the overlapping states. An additional peak in the TPES at 17.4 eV has not previously been observed. With this exception, the peak positions of the TPES are in good agreement with the He I data. The relative intensities of the TPES and He I spectra, however, differ significantly. In the He I spectrum of Potts et al.17 the ratio of the intensities of the XΣ2+, ΛΣ1/2, and G1/2 features are ~2:2:1, while the same analysis of the TPES gives ~1:4:2. Thus, the intensities of the XΣ2+, ΛΣ1/2, and G1/2 features compared to that of the Π peak are enhanced under threshold conditions. In addition, the band at 17.4 eV is not observed in the He I ex-
experiments. Hence, autoionization with the associated production of low-energy electrons appears to be an important process above \( \sim 14.5 \) eV, with its greatest effect in the range 17–18 eV.

A vibrationally resolved TPES was recorded for the \( \tilde{X}^2B_2 \) state from 12.6 to 14.0 eV with a resolution of 0.1 nm [Figs. 3 (inset) and 5(a)]. Several peaks are observed with a constant spacing of 1130 \( \pm 60 \) cm\(^{-1}\). Peak positions and assignments are listed in Table IV, the values being in excellent agreement with those obtained by other groups at improved resolution.\(^{14,16}\) According to theory,\(^{33}\) the extensive vibrational structure is caused mainly by a substantial reduction in the HCH bond angle upon ionization from 112° to 78°, with smaller changes in the FCF angle and the C–H and C–F bond lengths. The structure is, therefore, believed to

---

**FIG. 3.** Threshold photoelectron spectrum of CF\(_2\)H\(_2\). The resolution is 0.3 nm (main figure), 0.1 nm (inset). The assignment of the electronic states of the parent ion (see Table I) is shown.

**FIG. 4.** (a) Threshold photoelectron spectrum of CF\(_2\)H\(_2\). (b) Coincidence ion yields of CF\(_2\)H\(_2^+\) and CF\(_2\)H\(^+\). (c) Coincidence ion yields of CFH\(^+\)/CFH\(_2^+\) and CF\(^+\)/CFH\(^+\). The resolution of all spectra is 0.3 nm.

**FIG. 5.** (a) Threshold photoelectron spectrum of CF\(_2\)H\(_2\) between 12.6 and 14.0 eV recorded at a resolution of 0.1 nm. (b) Coincidence ion yields for CF\(_2\)H\(_2^+\) and CF\(_2\)H\(^+\) recorded at the same resolution.
arise from excitation of the near-degenerate \( \nu_2 \) (CH\(_2\) bend: \( a_1 \) symmetry) and \( \nu_3 \) (C–F stretch: \( a_1 \) symmetry) modes. Calculations determine these ionic vibrational frequencies to be 1288 and 1412 cm\(^{-1}\), respectively,\(^{2,3}\) to be compared with experimental values of 1262 and 1116 cm\(^{-1}\) in the neutral ground state.\(^{34}\) Pradeep and Shirley\(^{14}\) also invoke the presence of a third overlapping vibrational sequence in the photoelectron band, a 2\( \nu_4 \) combination band (CF\(_2\) bend: \( \nu_4 \) having \( a_1 \) symmetry); the value of 2\( \nu_4 \) in the neutral is 2 \( \times \) 528 or 1056 cm\(^{-1}\).\(^{13,34}\) Although not relevant to our work, several groups have commented on the absence of vibrational structure in the (2\( \nu_2 \)–\( \chi \))\(^2\)\( B_2 \) photoelectron band of CF\(_2\)D\(_2\) recorded at the same resolution as the CF\(_2\)H\(_2\) spectrum.\(^{14,16}\) The most likely explanation for this behavior in CF\(_2\)D\(_2\) is predissociation, causing a decrease in lifetime and, hence, a peak broadening.

### 2. Scanning-energy TPEPICO experiments

The scanning-energy TPEPICO spectrum was also measured from 12.4 to 27.5 eV at a photon resolution of 0.3 nm and an ion TOF resolution of 64 ns. Higher-resolution, fixed-energy TPEPICO-TOF spectra (Sec. IV B 3) reveal that the parent ion and fragment ions CF\(_2\)H\(^+\), CFH\(_2\)\(^+\), CF\(_2\)H\(_2\)\(^+\), and CF\(_3\)\(^+\) are formed. The presence of two hydrogen atoms, and hence, the relatively small change in ion TOF following the loss of one or more hydrogen atom, renders the construction of ion yields difficult. Nevertheless, two unambiguous plots for CF\(_2\)H\(_2\)\(^+\) and CF\(_3\)\(^+\) [Fig. 4(b)], and two composite plots for CF\(_2\)H\(^+\)/CFH\(_2\)\(^+\) and CF\(_3\)\(^+\)/CFH\(_2\)\(^+\) [Fig. 4(c)] have been constructed. By comparison with our study of Cl\(_2\)H where a similar problem occurs,\(^{1}\) it seems likely that the dominant components of the two composite plots are CFH\(_2\)\(^+\) and CF\(_3\)\(^+\), involving the fission of one and two bonds, respectively. Assuming this to be true, AE values for CFH\(_2\)\(^+\), CF\(_2\)H\(_2\)\(^+\), and CF\(_3\)\(^+\) could be determined. They are listed in Table V, along with values reported by EIMS studies. The ion yields show that the \( \chi \)\(^2\)\( B_2 \) state of the parent ion is either stable or dissociates to CF\(_2\)H\(^+\), the \( \tilde{A}/\tilde{B}/\tilde{C}\) states dissociate predominantly to CF\(_2\)H\(^+\) and CFH\(_2\)\(^+\), and the \( \tilde{D}/\tilde{E}/\tilde{F}\) states form predominantly CFH\(_2\)\(^+\) and CF\(_3\)\(^+\). A scanning-energy TPEPICO spectrum was also measured from 12.6 to 14.0 eV at a photon resolution of 0.1 nm and an ion TOF resolution of 64 ns. The time-of-flight range was adjusted so that only CF\(_2\)H\(_2\)\(^+\) and CFH\(_2\)\(^+\) could be detected, and ion yields [Fig. 5(b)] were determined. It can be seen that while the \( \nu = 0 \) to \( \nu_2 \) or \( \nu_3 = 2 \) levels of the \( \chi \)\(^2\)\( B_2 \) state of CF\(_2\)H\(_2\)\(^+\) are bound, the \( \nu_2 \) or \( \nu_3 = 3 \) and higher vibrational levels dissociate to CF\(_2\)H\(_2\)\(^+\).

*References 7, 8, 9, 10.*

The AE measured for CF\(_2\)H\(_2\)\(^+\), 13.08 ± 0.03 eV, is in good agreement with previous measurements\(^{8–10}\) and the best determination to date of the thermochemical dissociation energy, \( \Delta H^0 = 13.16 \pm 0.24 \) eV. Our observations are consistent with the fact that lower vibrational levels of the ground state of the parent ion are bound. Assuming that the CF\(_2\)H\(_2\)\(^+\) signal turns on at its thermochemical threshold, the AE can be used to refine the value for the 298 K enthalpy of formation of this fragment. Using values of \( \Delta H^0 \)\(_{\text{298}}\) for CF\(_2\)H\(_2\) (–450.7 kJ mol\(^{-1}\)) and H (218.0 kJ mol\(^{-1}\)),\(^{26}\) an upper limit for \( \Delta H^0 \)\(_{\text{298}}\) of CF\(_2\)H\(_2\)\(^+\) is determined to be 593 ± 3 kJ mol\(^{-1}\).

We commented above that the threshold in the CF\(_2\)H\(_2\)\(^+\)/CFH\(_2\)\(^+\) ion yield [Fig. 4(c)] is likely to represent the AE for CFH\(_2\)\(^+\), rather than for CF\(_2\)H\(_2\)\(^+\). There are two reasons for this. First, since the former fragment requires fewer bonds to be broken, it is expected to appear at a lower energy. Second, the onset is sharp, implying that only one bond is broken. The AE determined for CFH\(_2\)\(_2\)\(^+\), 14.7 ± 0.1 eV, is \( ~0.7 \) eV above the appropriate thermochemical dissociation energy, 14.02 eV. We note that Lossing has reported an AE of 14.06 eV\(^{10}\) in apparent contradiction to our work.

The threshold in the CF\(_2\)\(^+\)/CFH\(_2\)\(^+\) ion yield plot is expected to give an AE for CF\(_3\)\(^+\) rather than for CF\(_2\)\(^+\), since fewer bonds break to form the larger fragment. The AE determined for CF\(_3\)\(^+\), 18.2 ± 0.4 eV, is in good agreement with the one previous measurement of Lifshitz and Long, 17.7 eV.\(^{8}\) Comparisons with the thermochemical data (Table I) indicate that close to the appearance energy CF\(_2\)H\(_2\)\(^+\) must form with HF rather than with H+H. Although CF\(_2\)\(^+\) has been detected in previous experiments, it was not observed in this TPEPICO study. Previous electron-impact measurements are contradictory. Steele\(^{7}\) reports a value of 14.8 ± 0.4 eV, while Lifshitz and Long\(^{8}\) obtain 20.7 eV. The former measurement indicates that CF\(_2\)\(^+\) is probably formed with molecular hydrogen (\( \Delta H^0 = 13.88 \) eV), the latter that CF\(_2\)H\(_2\)–CF\(_2\)H\(_2\)\(^+\)H \( + \) e\(^–\) (\( \Delta H^0 = 18.36 \) eV) is likely to be the dominant dissociation channel. Unfortunately, our TPEPICO measurements are unable to resolve this discrepancy. On the other hand, CF\(_3\)\(^+\) has been observed in our experiments (Sec. IV B 3), but
problems with mass resolution prevented its AE being determined accurately. It should be noted, however, that the AE obtained by us for CFH\(^+\), 18.2±0.4 eV, is effectively a lower limit to the AE of CF\(^+\). Lifshitz and Long\(^8\) have reported an AE for CF\(^+\) from CF\(_2\)H\(_2\) of 18.8 eV. Of the three possible dissociation channels, only the two which form a neutral molecular product (HF or H\(_2\)) are thermodynamically allowed at this energy.

### 3. Fixed-energy TPEPICO experiments

TPEPICO-TOF spectra with a resolution of 8 ns were recorded at 12.74, 12.88, and 13.02 eV, energies which correspond to formation of the \(\tilde{X}^2\)\(_B\)_2 state of CF\(_2\)H\(_2\)+ in its three lowest-observed vibrational levels. As excitation takes place below the first dissociation threshold, a peak at the TOF expected for the parent ion, 12.68 \(\mu\)s, is observed. The full width at half maximum (FWHM) of the parent ion peak measured at 13.02 eV was determined to be 130±10 ns (Fig. 6). This value is in good agreement with that calculated for ions produced only with a thermal distribution of velocities at 298 K in an apparatus with an extraction field of 20 V cm\(^{-1}\).\(^{35}\) TPEPICO-TOF spectra were recorded at several photon energies between 13.16 and 15.69 eV, with the TOF range set so that only CF\(_2^+\), CF\(_2\)H\(^+\), and CF\(_2\)H\(_2^+\) were detected. Only CF\(_2\)H\(^+\) was observed. Unfortunately, values of \(\langle KE\rangle\) for CF\(_2\)H\(_2^+\)→CF\(_2\)H\(^+\)+H could not be determined accurately due to unfavorable kinematics, since the CF\(_2\)H\(^+\) fragment takes away only 2% of the kinetic energy released.

TPEPICO-TOF spectra were also recorded at a resolution of 8 ns for photon energies of 15.31, 15.61, and 17.46 eV [Fig. 7(a)]. The TOF range was set so that CF\(^+\), CFH\(^+\), and CFH\(_2^+\) could all be detected. In this energy range only the larger of the three ions, with a peak center of 10.05 \(\mu\)s, was observed. Experimental values for \(\langle KE\rangle\) and \(\langle f\rangle\) were determined and, along with predicted statistical and impulsive values of \(\langle f\rangle\), are listed in Table VI. Since only one of the vibrational frequencies was available for CFH\(_2^+\), \(\nu_2 = 1450±30\) cm\(^{-1}\)\(^{36}\) and none for the isoelectronic molecule BFH\(_2\), the statistical fractions had to be calculated assuming that \(\langle KE\rangle_{\text{stat}} \gg \hbar \nu_1\). As the values predicted for \(\langle KE\rangle_{\text{stat}}\) are quite large, this assumption is probably valid. The impulsive fractions were calculated using the assumptions given in Sec. IV A 3. At energies of 15.31 and 15.61 eV, the mechanism for dissociation of CF\(_2\)H\(_2^+\) to CFH\(_2^+\) + F seems to be predominantly impulsive (Table VI). Conversely, at the higher
energy of 17.46 eV, statistical behavior appears to dominate.

Finally, TPEPICO-TOF spectra were recorded at 19.07 and 23.84 eV, with the TOF range again set to observe CF$^+$, CFH$^+$, and CFH$^-$. [Figs. 7(b) and 7(c)]. The purpose of these measurements was not to extract dynamic information, but to determine the identity of the fragment ion. (By contrast with CF$^2$Cl$^2$ and CF$^2$Br$^2$, it was not possible to obtain this information from fixed-energy cross sections of the scanning-energy TPEPICO spectra due to the large degree of overlap of the features.) From Fig. 7, it is clear that at 19.07 eV CFH$^+$ and CFH$^+$ are produced, while at 23.84 eV predominantly CF$^+$, with a peak center of 9.79 μs, is formed.

**C. CF$^2$Br$^2$**

1. TPES

The electronic configuration of CF$^2$Br$^2$ is \((3a_1)^2(3a_2)^2(3b_1)^2(3b_2)^2(4a_1)^2(4a_2)^2(4b_1)^2(4b_2)^2\), where the numbering scheme does not include core orbitals.\(^{19}\) A TPES was recorded from 10 to 26 eV on both the high- and medium-energy gratings with a resolution of 0.3 nm [Fig. 8(a)], and the spectra were spliced together at 14 eV. Peaks are observed at 11.13, 11.57, 12.00, 12.35, 13.38, 15.35, 16.5, 18.8, and 20.0 eV, corresponding to formation of the \(\bar{X}, \bar{A}, \bar{B}, \bar{C}, \bar{D}, \bar{E}/\bar{F}, \bar{G}, \bar{H}/\bar{I}, \bar{J}\) states of the parent ion. All values are in good agreement with the He I and He II data of Cvitas et al.\(^ {19}\) Below 15 eV, the appearance of the TPES is similar to that of the He I spectrum,\(^ {19}\) except for a slight difference in the relative intensities of \(\bar{X}\) and \(\bar{A}\) peaks compared to the \(\bar{B}, \bar{C}\), and \(\bar{D}\) peaks. In the threshold spectrum this ratio is smaller, implying that autoionization is slightly more important for the higher excited states. Above 15 eV, the threshold spectrum shows a significant increase in the intensity of the peaks, as compared with the He I measurements. Hence, autoionization is prevalent in the valence states \(\bar{E}^2A_2\) through to \(\bar{J}^2B_2\). This pattern is similar to that observed in both CF$^2$Cl$^2$ and CF$^2$H$^2$.

2. Scanning-energy TPEPICO experiments

The scanning-energy TPEPICO spectrum was also measured from 10 to 26 eV at a photon resolution of 0.3 nm and an ion TOF resolution of 128 ns. Cross sections taken at fixed photon energies reveal that over this range CF$^2$Br$^+$, CF$^2$Br$^-$, CFBr$^+$, CF$^+$, and Br$^+$ are formed. Br$^+$ is the only example observed in these TPEPICO studies of a non-carbon-containing ion. Ion yields [Figs. 8(b) and 8(c)] and breakdown curves (Fig. 9) were constructed. From the former, it can be seen that the \(\bar{X}^2B_1\) state of the parent ion either remains bound or dissociates to CF$^2$Br$^+$ via cleavage of the weakest C–Br bond. The low-lying states of CF$^2$Br$^+$, \(\bar{A}^2B_1\) through to \(\bar{D}^2B_2\), dissociate solely to CF$^2$Br$^+$; the near-degenerate \(\bar{E}/\bar{F}\) states form both CF$^2$Br$^+$ and CFBr$^+$; the \(\bar{G}^2A_1\) and \(\bar{H}/\bar{I}\) states form CF$^2$ and

**FIG. 8.** (a) Threshold photoelectron spectrum of CF$^2$Br$^2$. The assignment of the electronic states of the parent ion (see Table I) is shown. (b) Coincidence ion yields of CF$^2$Br$^+$, CF$^+$, and Br$^+$. (c) Coincidence ion yields of CFBr$^+$, CF$^+$, and Br$^+$. The resolution of all spectra is 0.3 nm.
For both Br and CF2Br2 are known, 112 and VII, AEs of these fragment ions determined for the first time Br2, the thermochemistry for Br-containing fragments CF2Br::ciation channels. It is reasonable, therefore, to use the AE of likely to have any barrier, and there are no competing disso-
lation of the parent ion. This state clearly has a bound potential to excitation of CF2Br2.

± 8 kJ mol⁻¹, respectively, 26,27 we can determine that ΔrH°₂₉₈(CFBr+) ≤ 570±9 kJ mol⁻¹. In principle, using AEs for CFBBr+ and CFBr+, similar calculations can be performed to determine upper limits for the enthalpies of formation of these ions. Although technically correct, effects such as excitation into repulsive states, barriers along the exit channel of the potential-energy surface, and nonstatistical competition between dissociation channels may render the real thermodynamic values significantly lower than those calculated. Hence, these calculations were not performed.

The AE measured for CF+, 15.8±0.3 eV, is very close to the thermochemical dissociation energy for forming CF2+ with two bromine atoms (ΔrH° = 15.66 eV), hence, this is likely to be the dominant dissociation channel. Similarly, the AE measured for CF+, 19.2±0.4 eV, agrees, within error limits, with the dissociation energy associated with the formation of CF+ with three atomic products (ΔrH° = 18.92 eV). For Br+, with an AE of 17.5±0.5 eV, the situation is considerably more complicated since there are ten possible dissociation channels (Table I). In some cases there are likely to be large barriers along the exit channel of the potential-energy surface. In addition, dissociation energies for the two channels which involve CFBr and CF-Br are unknown, although comparisons with similar reactions indicate that their values probably lie below ∼17 eV. Over the range of energies where signal is observed, 17.5–21.0 eV, there are only four thermodynamically accessible dissociation channels:

\[
\begin{align*}
\text{CF}_2\text{Br}_2 & \rightarrow \text{Br}^+ + \text{CF}_2\text{Br} + e^- , \quad \Delta_r H^0 \approx -17 \text{ eV}, \\
\text{CF}_2\text{Br}_2 & \rightarrow \text{Br}^+ + \text{CF}_2 + \text{Br} + e^- , \quad \Delta_r H^0 = 16.23 \text{ eV}, \\
\text{CF}_2\text{Br}_2 & \rightarrow \text{Br}^+ + \text{CFBr} + \text{F} + e^- , \quad \Delta_r H^0 \approx -17 \text{ eV}, \\
\text{CF}_2\text{Br}_2 & \rightarrow \text{Br}^+ + \text{FBr} + \text{CF} + e^- , \quad \Delta_r H^0 = 18.97 \text{ eV}.
\end{align*}
\]

Based on our previous experience of bulky molecules, 1 it is unlikely that any dissociation channel involving a barrier along the exit channel of the potential-energy surface plays a significant role. Hence, the final reaction can be discarded. Of the three other processes, it is not possible to decide which is dominant until, at the very least, the thermochemistry is known more accurately.

3. Fixed-energy TPEPICO experiments

The TPEPICO-TOF spectrum with an ion TOF resolution of 8 ns was measured at a photoexcitation energy of 11.12 eV, with the TOF range set to detect the parent ion (Fig. 10). The spectrum represents a superposition of the three isotomers of CF2Br2 (CF2Br2Br 25%, CF2Br2Br25Br 50%, CF2Br2Br225Br 25%), hence, its FWHM cannot be related simply to the width of a single Gaussian distribution. 35 Instead, the sum of three Gaussian functions is compared with the spectrum (Fig. 10), with each Gaussian representing one isotomer of CF2Br2. The individual functions are calculated from Franklin, Hierl, and Whan, 35 the heights being determined by the relative natural abundance, the TOF centers being determined by the mass of the isotopomer, and the
widths by the translational temperature and the extraction field. The total simulated feature fits reasonably to the raw data.

TPEPICO-TOF spectra were measured for CF₂Br⁺ at photon energies of 11.12, 11.59, 11.99, 12.35, 13.33, and 15.50 eV, corresponding to initial formation of the X, A, B, C, D, and E/F states of the parent ion. A spectrum was also recorded for CFBr₂⁺ at 15.50 eV, but unfavorable kinematics prevent the value of (KE)_i into CFBr₂⁺+F from being determined accurately. Values of (KE)_i for the CF₂Br₂⁺→CF₂Br⁺+Br measurements have been determined and are listed in Table VIII. The fitting procedure allows for the fact that Br exists in two isotopic forms. Since the thermochemistry of CF₂Br⁺ was unknown, difficulties arose in calculating the excess energy and, hence, (f_i). For reasons discussed in the previous section, the AE of CF₂Br⁺, 11.00 ± 0.05 eV, is considered to be a good approximation to Δ_H^0 for CF₂Br₂→CF₂Br⁺+Br. Hence, the excess energy can be calculated by subtracting 11.00 eV from the photon energy; we note that it is not necessary to add the internal energy of CF₂Br₂ at 298 K to the value obtained for the excess energy, since the AE is a room-temperature measurement. Experimental values for (f_i), and those predicted for the statistical and impulsive models, are given in Table VIII. The statistical fractions were calculated using known vibrational frequencies for the v₁ and v₂ modes of CF₂Br⁺, 1480 and 1362 cm⁻¹, respectively. Vibrational frequencies of the other modes are unknown, hence, values determined for the isoelectronic molecule BF₂Br were used. Fractions for the impulsive models were calculated using the assumptions outlined in Sec. IV A 3 and Ref. 1. Table VIII suggests that there is a general trend from modified-impulsive to statistical behavior as the photon energy is increased. It should be noted that the fractions calculated for the statistical and pure-impulsive models are quite similar, rendering the differentiation of these processes difficult. The value of (f_i) measured for the dissociation of the near-degenerate E/F states of CF₂Br₂⁺ is extremely low, 0.07. This cannot be explained by any of the dissociation mechanisms.

V. DISCUSSION

A. Dissociation channels

A comparison of appearance energies of fragment ions with thermochemical thresholds can yield information about both the mechanism of dissociation and the identity of the

dissociation channel. For fragment ions formed by the fission of one bond only, clearly there is a unique dissociation channel. For a pure statistical dissociation mechanism, the fraction of available energy released into translational kinetic energy of the two fragments is relatively small, with the fraction decreasing as the size of the fragments (and, hence, the number of available vibrational modes) increases. This is the case where the weakest C–X bond in CF$_2$X$_2$ breaks to form CF$_2$X$^+$+X (X=Cl, H, and Br). For an impulsive mechanism, where isolated-state behavior is observed in excited electronic states of the parent ion, the fraction of the available energy released into translational energy of the two fragments is greater than in a statistical dissociation. This appears to be the case when the stronger C–F bond in CF$_2$X$_2^+$ breaks to form CFX$^+$+F. Due to unfavorable kinematics, this effect in the kinetic-energy release cannot be measured in CFBr$_2$+$^+$+F. It is, however, observed in CFH$_2$+$^+$+F and, to a lesser extent, in CFCI$_2$+$^+$+F. Similar effects have been observed in previous TPEPICO photofragmentation studies of state-selected CC$_2$I$_X$+$^+$ (X=F, Cl, Br) and CF$_2$I$^+$ (Y=Cl, Br).$^{1,38}$

For fragment ions formed by the fission of two or more bonds, necessarily, there exist more than one dissociation channel. Each has its own thermochemical threshold energy, hence, the identity of the dominant channel has a significant effect on the AE of the fragment. We have found that in many cases the dominant channel can be inferred by comparing values of $\Delta_r H^0$ with the AE of the fragment ion. In general, such dissociation channels conform to one of two limiting cases. The first, characterized by the absence of any barrier along the exit channel of the potential-energy surface, was found to occur in the dissociation of CC$_2$I$_F$ and CC$_2$I$_{Br}$.$^1$ Processes involving bond fission only and loose transition states, such as CC$_2$I$_F$→CC$^+$+2Cl+I$^-$+e$^-$ and simpler reactions such as CC$_2$I$_F$→CC$_2$I$^+$+Cl+I$^-$, fall into this category. The second, characterized by a large barrier along the exit channel, was shown to occur to some extent in the dissociation of CC$_2$I$_H$.$^1$ Processes where bond breaking occurs simultaneously with bond formation, e.g., CC$_2$I$_H$→CCIH$^+$+Cl$_2$+e$^-$, fall into this category. The difference in behavior of this group of molecules was rationalized by the small size of the hydrogen atom. Extending this analysis to the CF$_2$X$_2$ series begs the obvious question of whether fragmentation of CF$_2$H$_2$ will behave differently to that of CF$_2$Cl$_2$ and CF$_2$Br$_2$. The AEs of ions formed by fragmentation of CF$_2$Cl$_2$ and CF$_2$Br$_2$ are considered first. Most AEs either agree with, or are slightly in excess of, $\Delta_r H^0$ of the highest-energy process. (The one exception is the AE associated with the formation of Br$^+$ where, due to uncertainties in the thermochemistry, the situation is more complicated.) Hence, as with CC$_2$I$_F$ and CC$_2$I$_Br$, fission-only processes involving loose transition states appear to dominate. The situation is slightly different with CF$_2$H$_2$. Only one AE, associated with the formation of an ion which required the fission of more than one bond, was determined unambiguously by the TPEPICO experiment. The AE of the ion, CFH$^+$, was determined to be 18.2±0.4 eV. It was commented earlier that since this value was lower than $\Delta_r H^0$ associated with the highest-energy process which produces atomic products (19.24 eV), the lower-energy reaction CF$_2$H$_2$→CFH$^+$+HF$^-$+e$^-$ had to be involved. This process is likely to proceed via a more tightly constrained transition state, and to have a barrier along the exit channel of the potential-energy surface. As observed in the preceding paper,$^2$ for dissociation of neutral molecules as well as of ions, the hydrogenated molecule appears to behave anomalously. We rationalize this to be a steric effect caused by the small size of the hydrogen atom.

B. Determination of the dissociation dynamics from the values of $\langle KE \rangle_f$ and $\langle f \rangle_f$

The values of $\langle KE \rangle_f$ and $\langle f \rangle_f$ (Tables III, VI, and VIII) can indicate the mechanism of photodissociation of some fragmentation channels of CF$_2$X$_2$$^+$. We note that the mean total translational kinetic-energy release, $\langle KE \rangle_f$, can only be determined for a two-body process, and its value only meaningfully interpreted if the dissociation is a single-bond fission, e.g., CF$_2$X$_2^+$→CF$^+$+X, and not for processes such as CF$_2$X$_2^+$→CFX$^+$+FX. We have measured fixed-energy TPEPICO-TOF spectra for smaller fragment ions (e.g., CFX$^+$) than those reported in Tables III, VI, and VIII. Such ions can form only by multiple-bond fission, with possibly one simultaneous bond formation, and from the peak shape it is possible to determine the energy released into the fragment ion.$^{39}$ The data are not reported, however, since there is no simple method to infer the dissociation mechanism solely from the fragment ion kinetic energy. In this section, we only discuss the values of $\langle KE \rangle_f$ and, where the thermochemistry is known, $\langle f \rangle_f$, for reactions involving a single C–X or C–F bond fission.

First, we discuss CF$_2$Cl$_2$$^+$. The values of $\langle KE \rangle_f$ and $\langle f \rangle_f$ for dissociation of CF$_2$Cl$_2^+$ to CF$_2$I$^+$ suggest that the $\tilde{X}$, $\tilde{A}$, $\tilde{B}$, and $\tilde{C}$ states, photoionized at 12.28, 12.56, 13.19, and 13.48 eV, respectively, may dissociate by a pure-impulsive mechanism. Interestingly, there is little evidence for modified-impulsive behavior associated with the dissociation of $\tilde{X}$, $\tilde{B}_2$, and $\tilde{B}_1$ states. This is contrary to that observed for the analogous states in CC$_2$I$_F$,$^1$ where dissociation of the ground and first excited states was found to conform to the modified-impulsive model. The fact that the $C^2A_1$ state of CF$_2$Cl$_2$ dissociates by a pure-impulsive model supports the apparent selectivity of dissociation to CF$_2$I$^+$, rather than to CFCI$_2$,$^+$ which is also thermochemically allowed. Despite the lack of ab initio calculations, Cvitas, Gusten, and Klasine$^{12}$ claim with some confidence that the $\tilde{C}^2A_1$ state is formed by removal of an electron from an orbital whose character is predominantly Cl lone pair. The “hole” created is, therefore, localized on the chlorine atom, which can subsequently be dispersed by rapid charge delocalization. If dissociation occurs on a time scale faster than charge redistribution, CF$_2$I$^+$ will selectivity be formed. This selectivity can only be achieved for a rapid dissociation, hence, the observation of a value of $\langle f \rangle_f$, characteristic of a pure-impulsive process is expected. Dissociation of the $D^2B_2$ state of CF$_2$Cl$_2^+$ at 14.42 eV fits neither the pure-impulsive nor the statistical models, and appears to be a mix-
ture of the two. The difference in behavior of the $\tilde{D}^2B_2$ state may reflect an increase in the density of electronic states at this energy. The near-degenerate $\tilde{E}/\tilde{F}$ states of CF$_2$Cl$_2$ at 16.25 eV dissociate to both CF$_2$Cl$^+$ and CFCl$_2^+$. The values of $\langle KE \rangle$ and $\langle f \rangle$ (Table III) appear to indicate a competition between statistical and pure-impulsive dissociation mechanisms. Fragmentation of these states fits a statistical model for production of CF$_2$Cl$^+$, but closer to a pure-impulsive model for production of CFCl$_2$.$^+_F$. The $\tilde{E}^2B_1$ and $\tilde{F}^2A_2$ states are produced by the removal of a fluorine lone-pair electron.$^{12}$ Thus, rapid-impulsive dissociation, before charge redistribution can occur, now favors C–F bond fission and production of CFCl$_2$.$^+_F$, whereas a statistical process should result in production of both CFCl$_2^+$ and CF$_2$Cl$^+$. The experimental data seem to confirm these conclusions.

Unlike CF$_2$Cl$_2$, the TPEPICO spectroscopy of both CF$_2$H$_2$ and CF$_2$Br$_2$ is characterized by the detection of the parent ion at low photon energies, indicating that the ground state is stable with respect to dissociation in the lower part of the Franck–Condon region. Unfortunately, accurate values for $\langle KE \rangle$, and hence $\langle f \rangle$, could not be determined for the lowest dissociation channel of CF$_2$H$_2^+$, CF$_2$H$_2^+$ → CFH$^+$ + H, due to unfavorable kinematics. Values, however, were obtained for dissociation of some of the lower valence states of CF$_2$H$_2^+$ to CFH$_2^+$ at photon energies of 15.31, 15.69, and 17.46 eV. The proportion of available energy channeled into translation decreases as the photon energy is increased. At 15.31 eV, the mechanism appears to be largely purely impulsive, while at 17.46 eV statistical behavior seems to dominate. This transition may reflect an increase in the density of states as the energy of excitation increases.

Among the three molecules studied in this paper, CF$_2$H$_2$ has a unique electronic structure. The hydrogen atom has no lone-pair electrons so the first electron removed from the molecule originates from an orbital whose character is predominantly F lone pair. The lowest-energy dissociation channel, however, involves C–H rather than C–F bond fission. This situation, where the highest occupied molecular orbital has Y lone-pair character yet the weakest bond is C–Z ($\neq$ Y), is unique among the CF$_2$X$_2$ and CCl$_3$X series of molecules we have studied. For impulsive dissociation of the lower valence states of CF$_2$H$_2^+$, we might, therefore, expect C–F bond fission to be favored, but at energies below 14.02 eV only C–H fission is thermochemically allowed. This argument predicts that the AE of both CFH$^+$ and CF$_2$H$^+$ should be extremely close to their respective values of $\Delta H^0$, and that at low energies C–H bond fission should be effected by a largely statistical mechanism, while C–F bond fission should be largely impulsive. The experimental results only partially support this proposal. Dissociation to CFH$^+$ does indeed fit to an impulsive model at low energies but its AE, 14.7 eV, is ~0.7 eV above $\Delta H^0$. Lossing,$^{10}$ however, has reported an AE of 14.06 eV which corresponds closely to the thermochemical threshold. Unfortunately, the dissociation mechanism associated with fragmentation to CFH$^+$ could not be inferred, but its AE is extremely close to the best previously determined value of $\Delta H^0$, as expected. In similarity with CF$_2$Cl$_2^+$, there is little evidence for modified-impulsive behavior associated with the dissociation of CF$_2$H$_2^+$.

Photon-induced dissociation of CF$_2$Br$_2^+$ yields CF$_2$Br$^+$ for excitation into the $\vec{X}$, $\vec{A}$, $\vec{B}$, $\vec{C}$, $\vec{D}$, and $\vec{E}/\vec{F}$ states of the parent ion, and CFBr$_2^+$ for excitation into the degenerate $\vec{E}/\vec{F}$ states. The values of $\langle KE \rangle$, and $\langle f \rangle$, determined for dissociation to CF$_2$Br$^+$ fit well to a modified-impulsive model for the $\vec{X}$ state; a pure-impulsive model for the $\vec{A}$, $\vec{B}$, and $\vec{C}$ states; and a statistical model for the $\vec{D}$ state. The observation of modified-impulsive behavior, associated with dissociation of the $\tilde{D}^2B_2$ state of the parent ion, is noteworthy since it was not observed for any of the valence states of CF$_2$Cl$_2^+$ or CF$_2$H$_2^+$. This anomalous behavior may be due to the fact that the photon energy employed, 11.12 eV, is only 0.12 eV above the threshold for fragmentation. The value of $E_{\text{avail}}$, therefore, is much lower than in other experiments, circumstances where anomalously high values of $\langle KE \rangle$, can be observed.$^{1,40}$ The trend from modified- to pure-impulsive behavior with increasing energy fits the kinematic description of the two models. The observation of statistical behavior for dissociation of the $\tilde{D}^2B_2$ state of CF$_2$Br$_2^+$ at 13.33 eV probably reflects the fact that the density of states and anharmonicity of molecular vibrations increases as the energy of excitation in increased. The value of $\langle f \rangle$, determined from the $\vec{E}/\vec{F}$ states, 0.07, is extremely low and cannot be rationalized by any simple dissociation mechanism. Unfavorable kinematics prevent values of $\langle KE \rangle$, being determined accurately for the CFBr$_2^+$ TPEPICO-TOF spectra, and the lack of thermochemical data for this ion prevents any conclusions being drawn from its AE of 14.9 eV.

VI. CONCLUSIONS

Using tunable VUV radiation from a synchrotron source and TPEPICO spectroscopy, we have studied the fragmentation of the valence states of CF$_2$X$_2^+$ ($X=$Cl, H, Br) over the range of energies 10–25 eV. TPEPS, ion yield curves, and breakdown diagrams have been obtained with the experiment operating in the scanning-energy mode. In general, the peak positions in the threshold photoelectron spectra are in excellent agreement with those measured using He I radiation. A comparison of the relative intensities of the peaks indicates that the importance of autoionization producing near-threshold electrons is most pronounced in the range 14–20 eV. Autoionization is especially important in CF$_2$H$_2$, and appears to account for a previously unobserved feature in the threshold photoelectron spectrum at 17.4 eV. The ion yields show considerable evidence of state-selective fragmentation at low energies for CF$_2$Cl$_2^+$. The behavior of CF$_2$H$_2^+$ has not been fully characterized, and the interpretation of the ion yields from photodissociation of CF$_2$Br$_2^+$ is hampered by a lack of thermochemical data. In the cases where fragment ions can be produced by more than one dissociation channel, comparison of the appearance energy with $\Delta H^0$ indicates that for CF$_2$Br$_2^+$ and CF$_2$Cl$_2^+$ the highest-energy channel involving a loose transition state probably dominates. Conversely, in some circumstances CF$_2$H$_2^+$ dissociates via...
lower-energy channels involving a tightly constrained transition state. The difference in behavior is rationalized by the small size of the hydrogen atom.

At fixed energy, high-resolution TPEPICO-TOF spectra have been measured for those dissociations which involve the fission of a single C–X or C–F bond. In circumstances where the kinematics are favorable and the thermochemical data are either known or can reliably be inferred, values of the mean total translational kinetic-energy release, \( \langle KE \rangle \), and the fraction of the available energy partitioned into translation, \( \langle f \rangle \), have been determined. The values of \( \langle f \rangle \) are compared with those predicted for statistical, modified-impulsive, and pure-impulsive photodissociation models. In general, statistical values of \( \langle f \rangle \), are most likely when ionization occurs at a part of the molecule furthest away from the bond that breaks. Impulsive values of \( \langle f \rangle \), are more likely when the breaking bond lies close to the part of the molecule from which ionization occurs. Furthermore, there is a trend from impulsive to statistical behavior as the photon energy is increased. The results show clearly that these \( \text{CF}_2\text{X}_2^+ \) cations do not reach the “large molecule” limit until highly excited valence states have been attained. This behavior is extremely similar to that observed in both the \( \text{CCl}_3\text{X}^+ \) and \( \text{CF}_3\text{X}^+ \) series.\(^3\)\(^8\)
