Cinacalcet for Symptomatic Hypercalcemia Caused by AP2S1 Mutations

TO THE EDITOR: Familial hypocalciuric hypercalcemia is a genetically heterogeneous disorder with three variants: types 1, 2, and 3. Type 1 is caused by calcium-sensing receptor (CASR) mutations, and type 2 is caused by guanine nucleotide–binding protein (G-protein) subunit α11 (GNA11) mutations. Type 3, which is the most severe variant clinically, is caused by adaptor-related protein complex 2 (AP2), sigma 1 subunit (AP2S1) heterozygous mutations. AP2S1 mutations cause Arg15Cys, Arg15His, and Arg15Leu substitutions, and the mutant AP2-sigma proteins result in impaired calcium-sensing receptor–mediated signal transduction. There is currently no effective therapy for familial hypocalciuric hypercalcemia type 3. We therefore evaluated the usefulness of cinacalcet, a licensed calcium-sensing receptor allosteric activator, in correcting signaling defects due to AP2S1 mutations and in ameliorating symptomatic hypercalcemia.

We evaluated three previously unreported cases of familial hypocalciuric hypercalcemia type 3. Each of the three probands had an AP2S1 mutation causing an Arg15Cys, Arg15His, or Arg15Leu substitution (Fig. 1A). The probands included a 34-year-old woman who had a 12-year history of hypercalcemia. She presented with fatigue, headaches, and persistent generalized aches that did not resolve after parathyroidectomy. In addition, a 22-year-old man presented with hypercalcemia, fatigue, and generalized rib pain, and a 52-year-old woman who had an approximately 20-year history of hypercalcemia presented with headaches, abdominal pain, vomiting, fatigue, and musculoskeletal pain that did not resolve after pamidronate infusion or parathyroidectomy (Fig. 1A and 1B).

The in vitro effects of cinacalcet on the signaling responses of cells expressing the calcium-sensing receptor and familial hypocalciuric hypercalcemia type 3–associated AP2-sigma mutants were assessed by measurement of intracellular calcium concentrations and of the activity of the mitogen-activated protein kinase (MAPK)–serum response element reporter in response to alterations in extracellular calcium (see the Methods section in the Supplementary Appendix, available with the full text of this letter at NEJM.org). Cinacalcet (at a concentration of 10 nM) corrected the abnormal intracellular calcium signaling and MAPK responses to extracellular calcium in cells expressing the Cys15, His15, or Leu15 AP2-sigma mutants (Fig. S1 and S2 in the Supplementary Appendix).

Oral cinacalcet (at a dose of 30 to 60 mg daily) was administered to the three probands with familial hypocalciuric hypercalcemia type 3 over a 33- to 45-month period. This treatment led to more than 20% reductions in serum calcium concentrations (Fig. 1B) and abatement of symptoms. Cinacalcet also increased serum phosphate concentrations and reduced serum parathyroid hormone concentrations, although these values remained within the normal range (Fig. 1B).

Adverse effects such as nausea, vomiting, and hypocalcemia did not develop in any of the probands. However, long-term surveillance will be required to assess safety and monitor for hypocalcemia.

Our results show that cinacalcet-mediated allosteric modulation of the calcium-sensing receptor can correct the loss of function of AP2S1 mutations. In addition, in the short term, cinacalcet can reduce the symptoms of familial hypocalciuric hypercalcemia type 3 associated with all three AP2S1 mutations.
