 - Abstract

9 Improving the long-term performance of deep geothermal reservoirs, as an energy source, can lead to a 10 significant increase in efficiency of heat extractions from these assets. This will assist designers, energy 11 firms, managers, and government decision makers to plan and maintain the use of limited available 12 energy resources and hence enhance key sustainable development goals. Enhanced geothermal 13 reservoirs possess a multi-phase behaviour with complex inter-relationship between several parameters 14 that makes the analysis and design of these systems challenging. Often, this challenge is increased when 15 taking into consideration the optimum use of the available resources and induced costs during both 16 creation and exploitation phases. This research presents a novel design approach developed to achieve 17 efficiency and improved long-term performance in doublet enhanced geothermal systems (EGS). The 18 proposed approach is based on an optimisation procedure using a numerical hybrid methodology 19 integrating a multi-objective genetic algorithm with finite element analysis of fully coupled thermal 20 hydraulic processes of reservoirs. The results of the optimisation process are discussed in comparison 21 with data available from a benchmark case study. The results demonstrate a significant improvement in 22 the long-term performance of EGS reservoir, both in terms of thermal power and costs when optimised 23 using the proposed methodology.

28 1 Introduction

Geothermal power has been used for many centuries but, mostly extracted from shallow sources and natural hot springs [1]. It is, however, only recently that the technology to exploit hot-dry-rock (HDR) geothermal reservoirs has advanced sufficiently. In 1974, the first HDR deep geothermal reservoir in Los Alamos was developed, where the heat of the subsurface at the depth of between 4 to 5 kilometres was extracted to generate electricity power [2]. This was followed by trials of HDR in the UK at the Rosemanowes Quarry between 1977-1980 [3]. However, the modern process of extracting heat from a deep geothermal reservoir stems from developments in the 1990s where a hot dry rock matrix was
stimulated using hydraulic fracturing at depths over 2.5 kilometres where temperatures of 150-200 °C
exist. This resulted into the development of the so called Enhanced Geothermal System (EGS) [4],
where energy in the form of hot fluid or steam can be produced.

39 In general, geothermal energy, due to its nature, is much more predictable than other renewable sources of energy; hence it is a popular option in many countries [5]. For example, in China it is predicted that 40 geothermal reservoirs have the potential to produce enough energy for over 5000 years of China's 41 42 annual total energy consumption (i.e. 95.2×1018Joules in 2010), if just 2% of its EGS resources are 43 recovered [6]. However, due to requirements in advanced technology and economic challenges, as well 44 as uncertainties that exist at the depths used for EGS [7, 8], EGS is still considered to be at the 'proof 45 of concept' stage [9]. These challenges have resulted in deserting many geothermal projects, e.g. the Spa Urach project, Germany, which started in 1977 but was abandoned in 1981 due to financial 46 problems [10]. Other examples include the Basel Project in Switzerland and Southeast Geysers in the 47 48 USA, where they were abandoned because of technical difficulties, see [11] and [12]. Another key 49 challenge that faces EGS reservoirs is the time taken by the cold fluid front to reach the production well, 50 known as the thermal breakthrough [13]. This problem was first identified by Gringarten and Sauty [13] 51 during development of an analytical model for a sedimentary reservoir to optimise the distance between 52 the injection and production wells in a doublet system with a constant heat for long term production. 53 The thermal breakthrough of the reservoir has been observed in existing projects such as the geothermal 54 reservoir in the UK at Rosemanowes Quarry [14] and the Hijiori hot dry reservoir in Japan [15], which 55 led to abandoning both projects.

Due to significant costs involved in field trials of HDR reservoirs [7], computational modelling is 56 57 deemed to be an affordable option to enable researchers to investigate possible ways to extend the use 58 of EGS particularly during the preliminary stages to assess the thermal power and the economic 59 feasibility of EGS sites [7]. A comprehensive study conducted by [16] on numerical modelling of EGS 60 reservoirs, indicated that, in general, modelling can be divided into three different categories in terms 61 of EGS reservoir performance. The first category relates to improving the efficiency of heat extraction technologies for different rock deposits considering a wide range of contributing temperatures. The 62 63 second category aims to evaluate the commercial feasibility of the extracted thermal energy at various 64 stages of designing prospective resources. The third category estimates the thermal performance of 65 existing and potential future EGS reservoirs based on the initial thermal energy extraction rate [16]. In 66 recent decades, different researchers have proposed a variety of numerical modelling strategies to gain 67 an understanding and explore potential trade-off of the above three key categories [17-20]. These studies 68 offered some understanding, interpretation and insights into the complex processes taking place in specific EGS reservoirs. However, they did not probe directly the reservoir design parameters that 69 70 influence the long-term performance of EGS reservoirs [16].

71 Recently, several studies have used optimisation approaches in order to achieve efficiency in one or 72 more aspects of EGS performance. Chen and Jiang [21], used a parametric study to analyse the optimum 73 design of an EGS multi-wells reservoir. They found that the configuration of production wells in 74 relation to the injection well affects the reservoir efficiency in terms of heat extraction. However, they 75 did not consider the change in the distance between the injection and production wells, whilst it has 76 been shown that this parameter has a significant impact on the reservoir efficiency as stated by [13, 22, 77 23]. Biagi et al. [24], used a multi-objective genetic algorithm to optimise injection flow rate of Carbone dioxide (CO₂) as a working fluid in a geothermal reservoir. The optimisation technique was used to 78 79 reduce the impact of CO_2 on the environment in addition to the increase of the power generation for the 80 long-term performance of EGS reservoirs. Their work can be considered as a management model 81 assessment tool of the existing sites rather than a way to design EGS reservoirs during the early decision 82 stages. Chen et al. [23], used a Multivariate Adaptive Regression Spline (MARS) based statistical model 83 to optimise well positions of a potential geothermal reservoir near Superstition Mountain in Southern California, USA. They found that the MARS model provides significant improvement when dealing 84 85 with the uncertainty of design parameters. Li et al. [25], optimised the design of an EGS based on the 86 calculation of heat extraction efficiency for long-term performance using finite element analysis and 87 parametric study of a doublet horizontal wells reservoir. However, they have not considered the impact 88 of costs over the life of reservoir. Alivu and Chen [26], conducted a sensitivity analysis on the impact 89 of artificial and natural design parameters of Soultz reservoir on its long-term performance. They 90 concluded that the long-term performance of EGS can be enhanced through a strong control of the 91 investigated parameters, such as temperature and pressure of the injected fluid. However, to make a 92 decision during the preliminary stage to design a reservoir, there is still a need to develop a new 93 systematic approach that combines all design parameters in one model. In addition, in previous studies, 94 inter-relationships of contributing parameters are usually ignored; such oversimplification has been 95 shown to be insufficient to explain the overall reservoir behaviour [26]. The impact and interaction 96 between reservoir parameters that influence the overall performance, including the total power and 97 breakthrough time, are far more complex than simply considering these in isolation.

98 Therefore, it is clear that commercial EGS should combine both design and post-design models in order 99 to achieve an efficient system. Thus, this has motivated the proposal of the novel approach presented in 100 this paper to optimise both design and management of EGS reservoirs using a hybrid optimisation 101 technique. This study integrates finite element (FE) analysis and genetic algorithm (GA) optimisation 102 technique, to evaluate the influence of design parameters in order to achieve optimal EGS reservoir 103 design. Via this approach, it will be possible to choose an optimum EGS reservoir design, considering 104 various key parameters as input variables, with respect to the heat extraction efficiency, commercial 105 feasibility and reservoir long-term performance. Whilst there are several factors that have impact on the 106 long-term heat production of an EGS reservoir, it is vital to identify key contributing parameters to ensure suitability of the proposed project. It should be noted that the present study will focus on applying
the proposed technique to the heat extraction process of reservoirs. Results may vary should other
aspects of the system (e.g. energy conversion system on ground) be included in the analyses as reported
by Zhang et al., 2013 [27].

111 2 Methodology and model development

112 2.1 Integration of the Finite element method with genetic algorithm optimisation

The methodology used in the research presented in this paper is based on a combination of a coupled 113 114 heat and mass transfer finite element (FE) procedure with a multi objective genetic algorithm (GA), to optimise efficiency and performance of enhanced geothermal reservoirs. In this approach, firstly, finite 115 116 element models of EGS reservoir are built using randomly selected representative parameters via a 117 multi-objectives optimisation algorithm. Several scenarios are generated to model an EGS system using 118 the FE method and each model is evaluated against a set of criteria (i.e. optimisation objectives). 119 Successful models are taken forward while those models diverging from the optimisation objectives are 120 abandoned in the next generations. New models are generated using combinations of bioinspired natural 121 selection functions available in the GA. This process continues until an acceptable tolerance or 122 maximum number of generations (both defined by the user) have been achieved. The proposed hybrid 123 approach (i.e. combined FE and GA) allows the exploration of a wide range of FE models to investigate long-term performance of reservoirs in an efficient and intelligent manner – performing such analysis 124 125 using an ordinary FE method alone is unfeasible [28]. Figure 1, shows a flowchart that describes the 126 process. Further details about the proposed hybrid optimisation approach, and genetic algorithm in 127 general, can be found in Faramarzi et al. [29].

128

129

Figure 1. Flowchart for the integration of FE Analysis with Multi-objective GA

Based on the previous studies and taking into account the long-term performance of EGS reservoirs, three optimisation objectives are considered in this study; (i) thermal drawdown, (ii) accumulative thermal power, and (iii) total reservoir cost. These objectives have been selected for optimisation in this research based on the literature (e.g. [30-32]). Each of these optimisation objectives are briefly described below:

i. Thermal drawdown (*TD*): this parameter is defined as the declination ratio of the production
temperature during heat extraction and it is used to predict the reservoir thermal breakthrough
time [13]. *TD* is calculated using Eq. 1[13]:

$$TD = \frac{T_p - T_o}{T_{inj} - T_o} \tag{1}$$

Where, T_p , T_o and T_{inj} (°C) are the production, initial and injected fluid temperature (°C), respectively. To avoid encountering thermal breakthrough in a reservoir, it has been suggested that thermal drawdown must not reach 10% [13, 33, 34]. To account for this important performance criterion [30], 10% of *TD* is considered as the threshold value during the optimisation process used in this study.

143

144 ii. The thermal power (W_{hp}) is defined as the heat production power of the EGS and is calculated 145 based on the first law of Thermodynamics [31], see Eq. 2:

$$W_{hp} = q(h_p - h_{inj}) \tag{2}$$

146 Where h_p and h_{inj} (J/kg) are the production and injection specific enthalpies and q (kg/s) is the 147 mass flow rate of the fluid. The accumulative thermal power is calculated up to the end of the 148 reservoir service life, which occurs at the breakthrough time, where the thermal power (W_{hp}) of 149 the reservoir is assumed to be zero at 10% of *TD* [33]. The accumulative thermal power is 150 (ΣW_{hp}) calculated using Eq. 3:

$$\sum W_{hp} = \sum_{t=0}^{J} W_{hp} \tag{3}$$

151 J (years) is the number of years at the reservoir breakthrough time; t (years) is the time of 152 operation.

153

154 iii. The third optimisation objective is the total cost of EGS. The high capital cost of geothermal
155 reservoirs and particularly the drilling cost of EGS reservoirs is the main challenge that prevents
156 the geothermal power to move from the 'proof of concept' stage [9] to become a commercially
157 feasible source of energy. The total cost of a reservoir is defined into two parts: the creation
158 cost and the operation cost over time. This is explained in details below:

159

160 <u>Creation cost:</u> drilling cost has the highest fraction of the total capital cost of the creation stage [32].
 161 According to Tester and Herzog [35], the drilling cost is ranged anything from 42% to 95% of the power
 162 plant total creation cost of EGS reservoirs and it is a function of the reservoir depth. Lukawaski *et al.* 163 [36], suggested that the drilling cost of each well in the reservoir can be calculated using Eq. 4 [36]:

Geothermal well cost
$$(C_w) = 1.72 * 10^{-7} * D_h^2 + 2.3 * 10^{-3} * D_h - 0.62$$
 (4)

164 Where, D_h (m) is the depth of the reservoir base. Eq. 4 shows that the drilling cost increases non-linearly 165 with the increase in the reservoir depth. 166 <u>Operation Cost</u>: The operation cost of heat extraction (C_e) of an EGS reservoir is calculated based on 167 the following Equation by Kong *et al.* [37].

$$Ce = Q.\sum_{t=0}^{J} \frac{(\Delta P.pp + \rho_l.c_l.\Delta T.pr.\eta)_t}{(1+r)^t}$$
(5)

168 Where Q (m³/s) is the exploited fluid volume; ΔP (Pa) is the pressure change at the production well, pp169 (US\$/kWh) is the electrical power price, pr (US\$/GJ) is the heat price, r (%) is the discount rate with 170 time $\Delta T(K)$ is the change in production temperature and η is the efficiency of the power plant. The 171 values of pp, pr and r used in this research are reflecting prices in 2012 in Germany. It is worth 172 mentioning that the pressure in both injection and production wells are updated as per each finite 173 element simulation as well as during the optimisation process.

The third optimisation objective, which is the total cost (C_t) of the reservoir, can be calculated using Eq. 6:

$$C_t = C_w + C_e \tag{6}$$

In the present study, the long-term performance of EGS is achieved via maximising thermal power W_{hp} 176 and minimising both the thermal drawdown TD and the total cost C_t using a bi-objective optimisation 177 strategy. This was achieved using an EGS long-term performance criteria proposed by the 178 Massachusetts Institute of Technology (MIT) report [38], which considers the reservoir not-productive 179 180 when TD reaches 10%. In the optimisation algorithm proposed in this study, if the above condition is 181 reached in the first ten years of heat extraction process, the design is considered to be redundant. In other words, objectives i and ii are combined and will form one objective of the optimisation process 182 while the other objective will be the total cost. 183

184

185 2.2 Governing equations

In general, simulation of heat extraction in an EGS reservoir involves thermal-hydraulic-mechanical 186 and chemical (THMC) coupled processes [39, 40]. However, the coupled hydraulic and thermal 187 processes, which represent the fluid flow and heat transfer, play the most significant role in the heat 188 extraction stage for the long-term performance compared to the other processes [41-43], see further 189 discussion in Section 2.3.2.2. Thus, in this paper the mechanical and chemical processes have been 190 191 ignored and only the fully coupled thermal-hydraulic (TH) processes are modelled to assess the long-192 term performance of EGS reservoir. Two energy equations are used to describe both the heat transfer in solid rock matrix (conductivity) and the heat transfer between the solid rock matrix and the fracture 193 194 fluid (convection). The time-dependent heat transfer model requires the solution of two sets of differential equations representing the heat transfer in porous media (heat energy conservation) and themass conservation (fluid flow equation).

197 2.2.1 <u>Heat transfer</u>:

Heat energy conservation and mass balance are the governing equations for the coupled TH processes
involved in geothermal reservoir. The mathematical model of heat transfer in a porous medium is
represented by Eqs. 7-10 [3]:

$$\left(\rho c_p\right)_{eff} \frac{\partial T}{\partial t} + \rho_w c_{p_f} \mathbf{u}. \nabla T + \nabla. \mathbf{q} = \mathbf{Q}$$
(7)

$$\mathbf{q} = -k_{eff} \nabla T \tag{8}$$

$$\left(\rho c_p\right)_{eff} = \theta \rho_w c_{p_f} + (1-\theta)\rho_r c_{p_r}$$
⁽⁹⁾

$$\mathbf{k}_{eff} = \theta k_f + (1 - \theta) \mathbf{k}_r \tag{10}$$

Where ρ , ρ_f , ρ_r are the equivalent, fluid and rock matrix densities (kg/m³) respectively; c_p , c_{p_f} , c_{p_r} are the equivalent, fluid and rock matrix heat capacities at constant pressure (J/(kg.°C)) respectively; $(\rho c_p)_{eff}$ is the equivalent volumetric heat capacity at constant pressure; k_{eff} , k_f , k_r are the equivalent, fluid and rock matrix thermal conductivities (W/(m.°C)) respectively; **u** is the Darcy velocity; T is the temperature (°C); θ is the porosity of the rock matrix; Q is the heat source/sink term, and **q** is the conductivity heat flux of the rock matrix.

207 2.2.2 <u>Fluid flow</u>:

The mass conservation principle is applied to the hydraulic process. For mass balance, Darcy's Law is used assuming a laminar fluid flow. The mathematical model of fluid flow in a porous medium is represented by Eqs. 11-12 [3]:

$$\frac{\partial}{\partial t} (\theta \rho_f) + \nabla . (\rho_f \mathbf{u}) = Q_f \tag{11}$$

$$\mathbf{u} = -\frac{k}{\mu} \nabla p \tag{12}$$

where *k* is the permeability of the porous medium (m²); μ the fluid dynamic viscosity (Pa.s); Q_f the fluid sink/source term, and *p* is the fluid pressure (Pa).

Equations (7) to (12) are solved using the finite element method. Details of the finite element model arepresented in the next section.

215 2.3 The Finite Element Model (FEM)

The present research employs a single porosity model in which the geothermal reservoir is described as a porous medium with single porosity, taking into account both rock natural porosity and the presence of any fractures. In addition, the work presented in this paper considers an anisotropic equivalent permeability of the fractured zone.

220 2.3.1 Geometry and material properties

The Spa Urach geothermal reservoir in Germany is considered as a benchmark scenario for the present study due to the availability of the necessary data to re-create the finite element models [44]. A threedimensional finite element model is developed to simulate the reservoir between 3,850 m and 4,150 m depth as shown in Figure 2. The temperature gradient is 0.03 °C/m and the reservoir is a doublet well system which consists of an injection and production wells at a separation distance of 400 m, see Figure 2. The equivalent fracture zone permeability is assumed to be 1.53e-15 (m²) in the x direction and 3/8 of k_x in the y and z directions [45]. The material properties of the case study are presented in Table 1.

- 228
- 229

Figure 2. 3D geometry of the doublet well reservoir used in the FE model [45]

230

Table 1. Geometrical parameters and material properties of the FE model (adopted from [45]).

232 2.3.2 Initial and Boundary conditions

There are two sets of initial and boundary conditions in the present problem. The first set of initial and boundary values is related to the heat conduction process in the reservoir including the injection well. The second set of prescribed values consists of the initial and boundary conditions related to the hydraulic process in the reservoir, including prescribed pressures in the injection and production wells.

237 2.3.2.1 <u>Initial conditions</u>: The initial conditions related to both thermal and hydraulic processes are 238 represented in Figure 3. The initial temperature in the reservoir is assumed to vary linearly with depth 239 and a temperature gradient (T_g) of the Spa Urach site is 0.03 °C/m [45]. The reference temperature 240 (T_{ref}) at a depth of 4445.0 m is 162 °C and the initial distribution of the temperature in the reservoir is 241 given as a function of depth by Eq. 13 [45]:

$$T_o = T_{ref} + T_g(z - 4445) \tag{13}$$

242 Where, z is depth (m).

243 2.3.2.2 <u>Boundary conditions</u>: The fluid in the injection well is assumed to have a constant temperature
244 of 50 °C as stated by McDermott *et al.* [46]. This corresponds to a Dirichlet boundary condition related
245 to the heat conduction problem.

246 Fluid pressure in the injection well is assumed to have a prescribed value of 10 MPa at the top surface 247 of the reservoir (over-pressurised fluid). This pressure increases linearly with depth as stated by 248 McDermott et al. [46] according to Eq. 14. The production well is under-pressurised by -10 MPa on the top surface and linearly varies according to Eq. 15. On the lateral boundary of the reservoir, which is 249 supposed to be at a large distance from the injection and production wells, both isothermal and 250 251 hydrostatic conditions prevail during the whole time period. Hence, no fluid mass or heat flux take place 252 through this boundary [47-49], which is enforced by the Neumann boundary conditions Eq. 16 and Eq. 253 17.

$$P_{inj} = \rho_f g z + 10 \text{ (MPa)} \tag{14}$$

$$P_{pro} = \rho_f g z - 10 \,(\text{MPa}) \tag{15}$$

$$\mathbf{n} \, . \, \rho_f \mathbf{u} = \mathbf{0} \tag{16}$$

$$\mathbf{n} \cdot \mathbf{q} = \mathbf{0} \tag{17}$$

Where, P_{inj} and P_{pro} are the injection and production fluid pressures (MPa) respectively, and **n** is the outward unit normal vector to the boundary.

256

257

Figure 3. Initial and boundary conditions for the numerical model [45]

258 2.3.3 Meshing

The FE mesh is refined around the wells to accommodate the high pressure and thermal gradients, as shown in in Figure 4. The mesh size grows outwards to the area surrounding the wells in order to achieve a reasonable computational time.

262

263

Figure 4. FE mesh of the proposed model and details of the mesh of the wells

Since the hybrid approach can involve millions of runs of FE models, particular attention is paid to the meshing to maintain the accuracy of the response while keeping a reasonable computational time. Four different mesh sizes were examined: mesh 1 is a coarse mesh which consists of 9709 elements, mesh 2 is finer than mesh 1, and has 16672 elements, mesh 3 is obtained after further refinement and has 23881 elements, and mesh 4 is a very fine mesh with 39920 elements. These cases were compared with respect to the production mass flow within 50 years of heat extraction, and the results are shown in Figure 5.

- 270
- Figure 5. Mesh convergence with response to the production mass flow rate (graph corresponding to mesh 4 is covering curves 2 and 3)

From Figure 5, it is clear that once a certain mesh size is used, there is no further impact on the flow accuracy. As convergence is achieved with mesh 2, the mesh size corresponding to this mesh has been selected for the numerical simulations to be presented in the next sections (mesh 2, 3, and 4 are all providing relatively same curves at the scale presented in Figure 5 and as such it is not possible to distinguish between them).

278 **2.4** Validation of the FE model

279 To demonstrate the accuracy of the FE modelling process, COMSOL Multiphysics [50] was used to 280 replicate the numerical simulation of the Spa Urach geothermal reservoir as a validation problem. The 281 results obtained with COMSOL Multiphysics (referred to as present work in Figure 6) are compared 282 with those of [45] where GeoSys/RockFlow code [51] has been used in terms of a production 283 temperature for a production period of 15 years. The three-dimensional transient FE analysis 284 corresponding to this benchmark problem, is a fully THM coupled process. The fluid in the injection well has a pressure of 10MPa and a temperature of 50 °C and reservoir temperature gradient of 0.03 285 286 K/m is assumed. In general, the present results and those reported in [45] for the same problem are in 287 close agreement, as can be seen in Figure 6. The small difference between the results can be attributed to the modelling of the injection and production wells which are discretised with one dimensional 288 289 element 1D in Watanabe et al. [45] whereas, taking advantage of the problem symmetry, they could be 290 modelled as two dimensional 2D half cylinder surfaces in the present study, see Figure 4.

- 291
- 292

Figure 6. Comparison of the present FE model and [45]

293 In addition to the above, the present FE model is also validated against the FE simulation conducted by Chen and Jiang [21] for an artificial reservoir to verify the TH coupled processes with a temperature 294 gradient of 0.04 °C/m; an injection flow rate of 50 kg/s is considered at an injection temperature of 70 295 °C. The ground surface temperature is 27 °C. The reservoir has an equivalent permeability of 1e-14 m². 296 297 The simulation of the TH coupled process is performed using a combination of the heat transfer in porous media and Darcy's Law modules in COMSOL Multiphysics. Hence, mechanical effects are 298 299 neglected and the rock matrix is assumed to be rigid. Figure 7, indicates that the values of the production temperature from the FE model in this paper agree very closely with FE study conducted by [21] for 24 300 301 years of heat extraction.

302

303

Figure 7. Comparison of present FE modelling against [21]

304 3 Parametric study

A parametric study was performed to identify the key variables of the fitness function for the multi-305 306 objectives GA optimisation. The parametric study is limited to those variables of EGS reservoirs that 307 are typically human-controlled (i.e. design parameters); which in this study, include reservoir depth, distance between injection and production wells, fluid injection pressure and temperature, and the 308 309 equivalent permeability of both fracture and rock matrix network. Figure 8, shows the results of the parametric study. In these graphs, both objectives are normalised according to their maximum and 310 minimum values; the breakthrough time varies from 0 to 50 years and the accumulative power varies 311 312 from 0 to 200 MW, where these values were selected after a complete sensitivity analysis of the 313 reservoir design parameters. As mentioned in Section 2 earlier, taking into consideration the threshold 314 value of TD at 10 years of heat extraction, 0 for both normalised objectives will refer to the failure of the reservoir design before 10 years and 1 indicates the maximum values of the objectives. 315

The results are plotted for each key parameter while keeping other parameters constant at their reference values in Spa Urach project. The results show that the accumulative thermal power ($\sum W_{hp}$) is highly sensitive to the reservoir depth, well spacing, equivalent permeability of the fractured zone and the injection pressure. However, both objectives are less sensitive to the injection fluid temperature (Figure 8e). In addition, Figure 8a shows that the breakthrough time is less sensitive to the maximum reservoir depth. It is worth noting that, the maximum depth of the reservoir has significant impact on the drilling costs.

Figure 8. Sensitivity analysis for the EGS design parameters on both normalised thermal breakthrough time
 (dash line) and accumulative thermal power production (solid line) (all parameters are normalised with respect
 to their maximum values); where (a) reservoir depth, (b) distance between injection and production wells; (c)
 fluid injection pressure.; (d) equivalent permeability of the reservoir; (e) fluid injection temperature

Based on the sensitivity analysis, the maximum reservoir depth (D_h) , distance between the injection and production wells (d), fractured zone permeability (k_x) and fluid injection pressure (P_{inj}) are selected to be the optimisation variables. The constraints for these variables are presented in Table 2.

330 Table 2. Constraints of the variables in GA multi-objectives

- 331 The following points were considered during selection of these constraints:
- The depth of the reservoir is estimated between 4000-6000 m. This range is assumed as it is more practical for drilling process [52].
- The distance between the injection and the production wells in rectangular reservoirs (which is the case in this research) depends on the industry considerations where the production and the injection wells should be at the centre of two adjacent circles, which have the same radius, equal to a half of the reservoir width [53], see Figure 9.

338

- Figure 9. Industrial consideration for reservoir area based on the Influence zone of each well, after
 Wees *et al.* [53]
- Therefore, based on the industrial consideration, the minimum boundaries of the injection andproduction wells are chosen to be at 150m distance from the reservoir edge.

The injection pressure is varied between 1MPa to 20 MPa. The value of 20 MPa was determined

• The permeability of the fractured zone has values within the range 10^{-13} m² – 10^{-16} m² [54].

after several initial trial and error simulations.

344 345 •

346

347 4 Results and discussions

348 An algorithm was developed to integrate FE analysis with a GA to find optimum values of the bi-349 objective fitness function. The first objective is to minimise the total reservoir cost and the second objective is to maximise the accumulative thermal power production $(\sum W_{hp})$ of the reservoir at the 350 breakthrough time. As explained earlier in section 2.1, the thermal drawdown of the reservoir is 351 implicitly considered in the latter by applying the threshold value of 10%TD during the optimisation 352 353 process. The parameters of the Multi-objectives GA optimisation are summarised in Table 3. These values are chosen based on the number of variables, domain sizes and after a number of trial and errors 354 simulations. 355

356

Table 3. Parameters used for the Multi-objective GA in the present research

Two scenarios are considered for the optimisation process. In the first scenario, all the design parameters 357 (i.e. D_{h} , d, k and P_{ini}) are included during the optimisation of EGS design. The second scenario is carried 358 359 out in order to determine the optimum solutions in the absence of any changes to the reservoir fracture configuration (i.e. without changing the equivalent permeability of the reservoir). For both scenarios, 360 the GA-FE optimisation algorithm was run several times using different randomised initial points to 361 ensure global optimum solutions are achieved. The following sections present the results of the two 362 optimisation scenarios. The Pareto fronts of both scenarios are illustrated in Figure 10. Figures 10 (a, 363 b) have been normalised to the minimum and maximum values of each scenario while Figure 10c is 364 365 normalised with respect to the combined extreme values.

Figure 10. Pareto front of the optimum solutions of both scenarios (with and without changing the equivalent permeability of the reservoir), (a) 1st scenario, (b) 2nd scenario and (c) both case scenarios; where S11, S12 and S13 are the selected best designs in the 1st scenario and S21, S22 and S23 are the selected best designs in the 2nd scenario

Figure 10, show significant reduction in the value of the first objective (i.e. total cost) particularly in
the first scenario. However, for the second objective (i.e. accumulative thermal power) there is no
significant difference between the two scenarios, values of the second objective are restricted between

373 105-154 MW. In the first scenario, high accumulative thermal power designs have a cost between 75 to 374 88 Million \$USA, as can be seen in Figure 10a. However, in the second scenario, to achieve a productive 375 reservoir with high accumulative thermal power, a significantly higher investment is needed (about 110 to 185 Million \$USA), see Figure 10b. Figure 10c presents the optimal trade-off curves of both case 376 377 scenarios considered in the present study. The results show the considerable impact of permeability on 378 the reservoir total cost. It is important to emphasize that this analysis has overlooked the cost of fracturing the reservoir and is only considering the two scenarios together to highlight the influence of 379 permeability. The impact of the permeability on the other variables during the optimisation process, is 380 381 presented in Figure 11, where the values of the optimised parameters are normalised to the selected constraints for the GA. 382

383

Figure 11. Maximum values of the normalised variables for both scenarios (with and without changing the equivalent permeability)

386 The results show that in the first scenario, when all the sensitive parameters vary within the given ranges, the reservoir extended to a moderate depth. This resulted into a lower drilling cost compared to 387 the 2nd scenario, where the reservoir depth was much higher and corresponded to over 90% of the 388 normalised depth. This depth was necessary to achieve a higher production temperature, which resulted 389 390 into a higher drilling cost. In addition, both scenarios intend to reach about 0.9 of the normalised 391 distance between the injection and production wells in order to sufficiently reduce the thermal 392 breakthrough time. Furthermore, the maximum injection pressure in the second scenario is more than 393 twice of that in the first scenario. The high injection pressure in the second scenario is due to the low 394 permeability of the reservoir (about half of the maximum permeability of the first scenario) – this has a 395 significant impact on increasing the operation cost.

The process of choosing the best solution from the Pareto front is something open for debate, to some 396 extent subjective and most importantly depends on the design requirements for specific cases. In this 397 398 paper, the minimum distance selection method (TMDSM), also known as Knee point, was used to find the best optimum solution that satisfies both objectives [55]. All the solutions on Pareto front in Figure 399 400 10 can be considered an optimum design for both scenarios, considering the circumstances and the 401 design requirements. Should both objectives carry equal weights of importance, the minimum distance 402 to a preferred point, which is (0, 0) in this study, is considered to select the best solution in the Pareto 403 front. For the first and second scenarios these solutions are shown in Figures 10a and 10b (S11, S12, S13 and S21, S22, S23). For comparison, these solutions are presented in Figure 12. In this graph, 404 normalised values of cost and power are both shown for all the cases and are compared with those of 405 406 the benchmark case study of the Spa Urach geothermal reservoir. The optimum solutions are sorted 407 with respect to the total costs.

408

409 410 Figure 12. Normalised power and cost of the selected best designs (S11, S12 and S13 from 1st scenario on Figure 10(a); S21, S22 and S23 from 2nd scenario on Figure 10(b) and the case study

In addition, the thermal evolution of two of the best solutions (S11 and S21) are compared to the case study in this research. It can be seen in Figure 13 that the cold water front in S11 and S21 did not reach the production well. However, the case study has reached the breakthrough time in early stages which means that the methodology presented in this paper is proven to be an efficient tool to obtain optimum designs for EGS reservoirs.

418 5 Conclusions

419 The purpose of the present study was to develop an advanced systematic approach to enhance long-420 term performance of EGS reservoirs. Given that the above is a complex problem that involves several 421 factors, with inter-relationship between the factors and non-linear, nontrivial behaviour, it was not 422 possible to use conventional approaches to achieve an optimum design. Therefore, in this research, an 423 integration of FE analysis and GA optimisation technique was used to develop a methodology to find 424 optimum designs of EGS reservoirs. This hybrid optimisation approach gives an insightful understanding of EGS long-term performance regarding the reservoir extraction efficiency, commercial 425 feasibility and its service life. The research achieved the above objectives by combining both design 426 427 and post-design models together.

From the results of the sensitivity analysis, it was shown that higher permeability of the fractured zone, higher fluid injection pressure and shorter distance between the injection and production wells can all produce higher thermal power at early stages. However, these parameters also have significant influences on the thermal drawdown and thus lead to the acceleration of the breakthrough time of EGS reservoirs. Therefore, there is a peak point for the accumulative thermal power when studying each of the above parameters. On the other hand, higher depth of EGS reservoir enhances the accumulative thermal power production, while it also results in high creation cost.

Taking into account the results of the sensitivity analysis, two scenarios (with and without changing the equivalent permeability of the reservoir) were considered during the optimisation process to find potential optimum design of EGS reservoirs. It was observed that the permeability of the reservoir has a significant influence on the required capital costs for EGS designs. The research also shows that there is a complex interaction between the reservoir design parameters, which might create challenges for decision makers regarding both design and post design stages. The proposed methodology, in this paper, can be used to transform the way EGS reservoirs are currently exploited leading to a sustainable use of

- these assets. Moreover, it has the flexibility and potential to be adapted during the operation of the EGS
- 443 reservoir and/or as further information becomes available.
