Strongly squeezed states of light are a key technology in boosting the sensitivity of interferometric setups, such as in gravitational-wave detectors. However, the practical use of squeezed states is limited by optical loss, which reduces the observable squeeze factor. Here, we experimentally demonstrate that introducing squeezed states in additional, higher-order spatial modes can significantly improve the observed nonclassical sensitivity improvement when the loss is due to mode-matching deficiencies. Our results could be directly applied to gravitational-wave detectors, where this type of loss is a major contribution.

DOI: 10.1103/PhysRevLett.121.263602

Nonclassical, squeezed states of light have progressed from being just peculiar quantum states to a quantummechanical technology that increases the sensitivity of interferometric measurements without the need for increasing laser power. This is a remarkable feature with application in several areas [1].

For example, gravitational-wave detectors already operate with extremely high laser power that is limited both by engineering difficulties of the laser sources as well as the induced thermal load on the interferometer mirrors [2,3]. While an increase in laser power by a factor of 10 (corresponding to a  $10^{3/2} \approx 32$  increase in the observable Universe at shot-noise limited detection frequencies) seems extremely challenging, the same improvement could be achieved with the injection of squeezed light with a noise-reduction factor of 10 dB. Such strongly squeezed states are now routinely produced at near-infrared wavelengths [4–8]. In 2010, GEO 600 was the first gravitational-wave detector to employ squeezed-light input [9,10]. A test of squeezed light at the LIGO detector was successfully performed just before the upgrade to Advanced LIGO started [11], and an installation of squeezed-light sources at the Advanced LIGO and Advanced Virgo detectors is currently in progress [12,13].

Because squeezed states of light rely on quantum correlations between the individual photons, they are more sensitive to optical loss than coherent states: when photons are lost, these correlations are also destroyed. Tabletop experiments routinely achieve less than 10% total loss from production to detection of the squeezed states, allowing squeeze factors in excess of 10 dB and recently achieving 15 dB [8]. Yet, transferring these high values to quantummetrology applications remains a challenge. For example, the best squeezing in the large-scale interferometer GEO

600 was measured to be 4.4 dB [14]. This stark contrast is due to a much higher optical and interferometric complexity, which brings the total loss to a value of > 30%[9,11,14]. Similarly, quantum enhancement in biological measurements [15] and magnetometry, using both atomic systems [16] or microresonators [17], has been limited by optical loss.

Some optical loss—such as absorption, scattering, and polarization mismatch—stems from imperfect optical elements and its impact can hopefully be reduced with additional engineering work. Another source of optical loss is imperfect matching between the wave fronts of the involved light fields, i.e., mode mismatch or axial misalignment. This loss channel is often difficult to control; e.g., in gravitational-wave detectors, sophisticated automatic alignment systems are in use [18,19], as well as adaptive mode matching with movable lenses [20] and/or thermal deformation of optical elements [21]. The latter two methods are, however, limited to quasistatic corrections and cannot adapt well to dynamically changing light fields.

An alternative way to alleviate the loss of squeezing due to mode mismatch is to additionally squeeze a small number of higher-order transverse modes of light. Töyrä *et al.* [22] theoretically analyzed the improvement that can be achieved for squeezing the Hermite-Gaussian  $HG_{20}$  and  $HG_{02}$  modes in addition to the fundamental mode  $HG_{00}$ . In their simulations, they are able to recover almost the full nonclassical sensitivity gain, for mode mismatching loss as high as 15%.

Here, we experimentally demonstrate the reduction of mode-matching loss in an interference experiment by additional squeezing of a higher-order transverse mode. Our proof-of-principle experiment almost fully compensates a

Luruper Chaussee 149, 22761 Hamburg, Germany

(7%) mode-mismatching loss between a squeezed field and the local-oscillator field of a balanced homodyne detector (BHD) [23]. Since the underlying theory of mode coupling is exactly the same, our results are also applicable to mode mismatch in cavity setups.

*Conceptual description.*—The idea behind squeezing of higher-order spatial modes for mode-mismatch compensation can be illustrated with the help of Fig. 1 in the

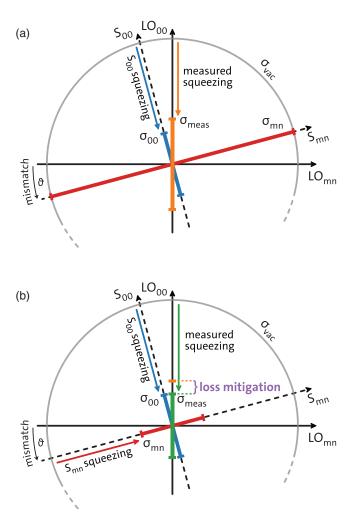

FIG. 1. Illustration of the concept behind mode-matching loss compensation with squeezed higher-order modes. Two orthogonal axes represent the electric fields in two orthogonal transverse spatial modes. The vacuum uncertainty of any combination of modes is represented by the outer circle  $\sigma_{\rm vac}$ . Mode  $S_{00}$ corresponds to the mode carrying the signal of interest and should ideally be aligned with the mode LO<sub>00</sub> of the local oscillator in balanced-homodyne detection, which defines the mode that is actually measured. Mode mismatch, represented by a rotation by angle  $\vartheta$ , then couples quantum noise  $\sigma_{mn}$  from higher-order mode (s) into the measured quantum noise  $\sigma_{\text{meas}}$  in LO<sub>00</sub>, as given by Eq. (1). (a) When only mode  $S_{00}$  is squeezed, and  $S_{mn}$  is in a vacuum state, the mode mismatch leads to a significant contribution of vacuum uncertainty to  $\sigma_{\text{meas}}$ . (b) When both  $S_{00}$  and  $S_{mn}$  are squeezed (here with identical squeeze factors), the optical loss due to mode mismatch is mitigated.

following way. A BHD selectively amplifies and measures all components of a signal field that are contained in the spatial mode  $LO_{00}$ , which is defined by its so-called local oscillator (LO) beam. Usually, this mode is prepared in a well-defined HG<sub>00</sub> state. Since all other HG<sub>mn</sub> modes are orthogonal to HG<sub>00</sub>, they do not interfere with the LO and do not contribute to the output of the BHD.

When the signal beam is mismatched with respect to the local-oscillator field, it needs to be described by its own set of transverse modes  $S_{mn}$ . For a small mismatch, the relation between the two sets of modes can be conceptually represented as a rotation by a mismatch angle  $\vartheta$ . It connects the measured noise uncertainty  $\sigma_{meas}$  to the noise uncertainties  $\sigma_{00}$  and  $\sigma_{mn}$  in the signal field  $S_{00}$  and its higher-order modes  $S_{mn}$ , respectively, by the relation

$$\sigma_{\rm meas} = \sqrt{\sigma_{00}^2 \cos^2 \vartheta + \sigma_{mn}^2 \sin^2 \vartheta},\tag{1}$$

where the noise in the individual modes is assumed to be uncorrelated.

When  $S_{mn}$  is in a vacuum state,  $\sigma_{mn} = \sigma_{vac}$ , this relation implies that the mismatch is equivalent to an optical loss  $\epsilon = \sin^2 \vartheta$  acting on the (squeezed) mode  $S_{00}$ . Figure 1(a) visualizes this with the rotated, dashed coordinate system. The combined projection of the noise in the  $S_{00}$  and  $S_{mn}$ modes onto the LO<sub>00</sub> mode results in a measurement noise  $\sigma_{meas}$  that exceeds the original squeezed noise  $\sigma_{00}$  in the signal beam by far. For more complex mismatches, the same considerations apply and extend to multiple mode dimensions.

From Eq. (1), the solution becomes obvious: if the noise in  $S_{mn}$  is also squeezed, then its contribution to the measurement noise can be significantly reduced. This is visualized in Fig. 1(b), where the squeezed  $\sigma_{mn}$  leads to a reduction of the noise components along the LO<sub>00</sub> axis. With the exemplary squeeze factors chosen here for illustration, the initial squeezing is fully restored.

Generating squeezed states of light in higher-order spatial modes was investigated in the context of measuring lateral displacement and tilt of a laser beam [24]. More recently, applications of spatial squeezing in quantum imaging have been studied, see, e.g., [25]. Higher-order modes can also serve as additional (quantum) communication channels in quantum information networks, either increasing the channel capacity by the number of modes that are used, or representing individual modes of a multimode entangled state [26].

There are two main approaches to the production of squeezing in higher-order spatial modes: via reshaping or via direct squeezing [27]. In the first approach, squeezing is conventionally generated in the fundamental mode, and then converted into higher-order modes with the use of phase plates [24] or spatial-light modulators [27]. Especially the latter allows for a very flexible generation of almost arbitrary mode shapes; however, the overall

efficiency and optical loss is limited by the resolution of the spatial-light modulator. In the direct approach, e.g., [28], the nonlinear parametric cavity is aligned such that it resonates on the desired higher-order mode. This approach yields very pure states that can in principle have the same amount of squeezing as the fundamental mode; however, it is only viable for low mode orders and does not support arbitrary mode shapes.

Experimental setup.—Our experiment followed the direct approach, with the setup depicted in Fig. 2. Two squeezed-light sources produced continuous-wave squeezed states of light at a wavelength of 1064 nm, using the same optical assembly as described in detail in [29]. Here, we label the two sources by the mode that they produced: while  $S_{00}$  was held resonant for a HG<sub>00</sub> mode, the cavity of  $S_{mn}$  was held on resonance for a higher-order mode, specifically we chose the  $HG_{01}$  mode. This was achieved by intentionally introducing a vertical displacement in the control field at 1064 nm, which enters the cavity and is used both for locking and as an alignment reference. To obtain sufficient nonlinear gain inside the squeezing cavity, also the pump field at 532 nm had to be vertically adjusted. For both control field and pump field, the coupling to the cavity's  $HG_{01}$  mode was about 30%, which is about three quarters of the maximally achievable mode overlap between a  $HG_{01}$  mode and a displaced  $HG_{00}$  mode. In theory, this coupling could be as good as 43%.

The squeezed field  $S_{00}$  was first sent through a Faraday isolator, and then reflected off the  $S_{mn}$  cavity (as  $S_{mn}$  was not resonant for the  $S_{00}$  mode) [30]. A piezomounted mirror between the two squeezers served to adjust the relative

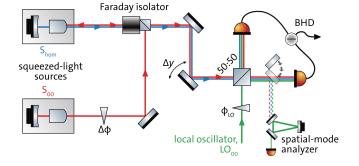

FIG. 2. Schematic of our proof of concept of using squeezed states of light in higher-order transverse modes to compensate for optical loss caused by mode mismatch. Squeezed-light source  $S_{00}$  produced output states in the fundamental HG<sub>00</sub> mode, while squeezed-light source  $S_{mn}$  produces output states in the HG<sub>01</sub> mode. The two fields were combined with a Faraday isolator and then sent towards a balanced homodyne detector (BHD). The BHD's local oscillator LO<sub>00</sub> was contained in the HG<sub>00</sub> fundamental mode. Mode-matching loss was intentionally introduced by a vertical misalignment of one of the steering mirrors by  $\Delta y$ . The resulting mode content could be examined with a spatial-mode analyzing cavity in one of the paths of the BHD, when the two squeezing resonators were operated with a strong carrier field but without pumping.

phase of the two squeezed fields  $\Delta \phi$ . The combined fields  $S_{00}$  and  $S_{mn}$  then traveled through the Faraday isolator towards a balanced homodyne detector, where they were overlapped at a 50:50 beam splitter with a strong localoscillator field. Both beam-splitter outputs were detected with photodetectors and the difference in photo currents was taken. After amplification, the output power spectrum was measured with a spectrum analyzer at a sideband frequency of 5 MHz. One of the beam-splitter outputs could be optionally sent towards a spatial-mode analyzer, which was a ring cavity specifically designed such that there was almost no mode degeneracy up to very high mode orders. This spatial-mode analyzer was used to investigate the mode content of all fields arriving at the BHD and additionally served as an alignment reference. The localoscillator field came from a mode-filtering cavity as well, and could therefore be prepared in a very pure mode state. Figure 3 shows that our setup generated about 4.8 dB of squeezing in the HG<sub>01</sub> mode, which to our knowledge is the highest amount of squeezing in a higher-order spatial mode reported so far.

*Results.*—In the first step, we activated only  $S_{mn}$  and prepared the local oscillator in the LO<sub>00</sub> (HG<sub>00</sub>) mode, with no vertical displacement  $\Delta y$ . In this configuration, we made sure that we were unable to detect squeezing from  $S_{mn}$ , due to the vanishing mode overlap, see the left panel of Fig. 4. We then turned on  $S_{00}$  as well. After reflection from  $S_{mn}$  and traveling twice through the Faraday isolator, we measured about 5.8 dB of squeezing.

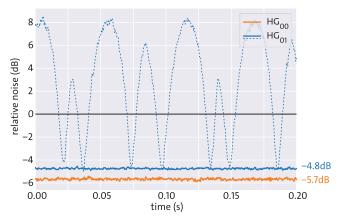

FIG. 3. Characterization of squeezed states of light from squeezing resonator  $S_{mn}$ , when resonating in the HG<sub>01</sub> transverse mode, compared to resonating in the HG<sub>00</sub> mode. In each case, the local oscillator was provided in the corresponding mode to achieve an optimal mode overlap at the balanced homodyne detector. The dashed blue curve was produced by scanning the local-oscillator phase  $\phi_{LO}$ , thus showing the oscillation between squeezing and antisqueezing. All traces were acquired with a resolution bandwidth of 300 kHz and a video bandwidth of 300 Hz, at a zero-span frequency of 5 MHz and with the local-oscillator power set to 2.25 mW. Except for the scanning trace, an averaging filter of 5 was active.

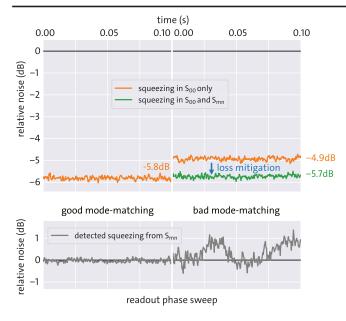

FIG. 4. Confirmation of mitigating mode-matching loss via squeezed higher-order modes. Top left, 5.8 dB of squeezing can be detected for the case where there is no vertical displacement introduced in the squeezing path,  $\Delta y = 0$  and thus  $S_{00} = \text{LO}_{00}$ . Top right, a small vertical misalignment  $\Delta y$  is introduced and the detected  $S_{00}$  squeezing drops to 4.9 dB. Introducing the additional squeezed-light field in  $S_{mn}$ , almost the full initial squeezing a sweep of the readout phase when only  $S_{mn}$  is squeezed. This measurement confirms that there is negligible contribution from the squeezed field in  $S_{mn}$  for the good mode-matching case, while it becomes visible in the bad mode-matching case.

In the next step, we intentionally introduced a vertical displacement  $\Delta y$  in the path between the Faraday isolator and the BHD by slightly misaligning a steering mirror in that path. The effect on the detected squeezing from  $S_{00}$  and  $S_{mn}$ , when looked at individually, can be seen in the right part of Fig. 4. First, the squeezing from  $S_{mn}$  became visible again, although only with very low squeezing values (the figure shows a sweep of the LO phase  $\phi_{LO}$  of the BHD for this curve, which then also shows the antisqueezing, making it more visible). Second, the detected squeezing from  $S_{00}$  dropped from 5.8 dB down to 4.9 dB. From the measured squeezing to antisqueezing for  $S_{00}$ , we were able to estimate an additional  $(7 \pm 1)\%$  of loss that was introduced by the misalignment. This was also independently verified via the spatial-mode analyzer, which showed an increase in higher-order modes (mostly HG<sub>01</sub> as expected) by the same 7%. We then switched on both squeezed-light sources at the same time and carefully adjusted the relative phase between the two until we obtained the green trace in Fig. 4. This curve reached a squeezing level of 5.7 dB, i.e., by combining the misaligned  $S_{00}$  squeezing with a squeezed  $S_{mn}$  beam, we were able to recover almost all squeezing that was lost because of the misalignment. The remaining 0.1 dB can be explained by the small amount of additional modes with m + n > 1, which were introduced by the misalignment, but not compensated by the single additional squeezed field.

Summary and conclusion.—We have shown that mitigating optical loss from mode mismatch between a mode carrying squeezed states and a bright local oscillator is indeed experimentally feasible by introducing additional squeezed fields in higher-order modes. Our setup used two squeezed fields in a  $HG_{00}$  and  $HG_{01}$  mode, respectively, and was able to almost completely compensate for incurred loss due to mode misalignment and brought the measured squeezing level back to within 0.1 dB of the initial value. Although misalignment can usually be compensated quite well with autoalignment methods, our scheme can be extended and applied to a compensation of, e.g., wave-front–curvature mismatch by chaining together additional squeezed-light sources operating in the  $HG_{20}$  and  $HG_{02}$  modes.

In measurement applications where squeezed states of light are used to increase the shot-noise limited sensitivity, a precise matching of the optical transversal mode to the instrument can be very challenging. In these situations, the setup shown here could be adapted to provide a squeezed field in a specifically tailored transversal-mode configuration, to compensate for encountered loss due to mode mismatch. It is straightforward, although costly, to extend our setup to more higher-order modes, by cascading additional squeezed-light sources via Faraday isolators. Our scheme could enable much higher enhancement factors in quantum metrology, such as in squeezed-light enhanced gravitational-wave detection, where strong squeeze factors are produced but are severely degraded because of optical loss.
